Miller supported the first hypothesis, although this does not mean that the second was entirely false, as both could be accurate to a degree.

In his work developing the conspicuous consumption concept, Miller employed costly signalling theory as developed by the biologists Zahavi and Zahavi (1997). Costly signaling theory states that only very fit and healthy animals have the ability to "waste" a lot of time, effort, and resources on developing costly signals, or handicaps, such as the peacock's tail, or in human beings the highly developed muscles of the body-builder (Miller 2009, p. 91). Miller further explained that:

... inspired by costly signalling theory my colleagues ... ran a series of four experiments whose goal was to see how people's consumption decisions might shift as the potential mating benefits of costly signalling became more or less salient ... [it was shown that] conspicuous consumption (for men) and conspicuous charity (for women) can be increased by thinking about mating opportunities, and so can function strategically as a form of mating display (Miller 2009, p. 107)

These experiments demonstrated that, on average, men in what was called a mating condition, where they were actively thinking about finding a sexual partner, spent more on conspicuous luxuries than men not in a mating condition, and thereby not actively thinking about mating or seeking a sexual partner. Another experiment conducted elsewhere demonstrated that men's testosterone levels responded directly to conspicuous consumption, as testosterone levels increased when expensive sports cars were driven by men in public settings (Saad 2011, p. 72).

Miller explicitly linked costly signalling theory in biology with Veblen's original monetary conception of conspicuous consumption, explaining in this respect that:

Signal costs can certainly include costs in terms of an animal's general energy budget (food calories

eaten) or ecological resources (such as mating territories acquired by threats and fights), which are similar in some ways to money. When such moneylike costs are paramount, costly signalling theory most resembles Thorstein Veblen's theory of conspicuous consumption. In *The Theory of the Leisure Class*, Veblen argued that luxury goods and services are acquired by the rich mainly to display their wealth, not to increase their happiness ... Costly signaling theory simply generalizes Veblen's insight to the biological world. (Miller 2009, p. 114).

As Miller explained, buying expensive products in order to display status is a means of suggesting by the display of wealth that a particular individual's physical and mental traits are superior to most others, as these traits have produced the ability to obtain the great wealth that is on display through the status-indicating luxury product (Ibid., p. 73).

Miller also outlined that one important way that conspicuous consumption now operated was through the development of brand names and associated brand equity, or the psychological value of a particular brand's name recognition to consumers (Ibid., p. 125; Miller 2007; Barnett and Weedon 2014). This value can be quantified using data such as the percentage of people that recognize a specific brand name and the percentage of the market for a given good that is captured by a particular brand.

Conspicuous Consumption of Fine Wine

Finally, this entry will briefly apply the conspicuous consumption logic to a particular luxury commodity: fine wine. Thorstein Veblen explicitly listed connoisseurship of expensive beverages as something that the gentleman of leisure should be seen to cultivate, with a \$20,000-per-bottle burgundy (e.g., Domaine de la Romanée-Conti, DRC) now constituting the epitome of an expensive beverage (Veblen 1925 [1899], p. 74). Geoffrey Miller listed rare burgundy as a luxury drink employed in order to publicly demonstrate an individual's consumer narcissism (Miller 2009, p. 58).

DRC's Romanée-Conti wine is produced in very small quantities, with only around

500 cases each vintage being available for the entire world market (\$240,000 per case), meaning that, at most, only the wealthiest 500 people in the world get to buy it on its initial release. All the wines of DRC are examples of a Veblen good, for which demand increases as the price increases.

The serious fine wine collector has various different opportunities to engage in conspicuous consumption as a form of honorific display. They usually have a dedicated wine cellar to house their fine wine collection, with prestigiously labelled bottles on display that connote to any invited visitors the precise degree of wealth of the collector (Spurrier 1986). In addition, they have the opportunity to serve select examples of their fine wines to guests at various social functions such as dinner parties and yearly celebrations.

The fine wine collector also has the opportunity to buy and sell fine wine at public auctions and to buy fine wine in the public futures market. Finally, there are now numerous fine wine tastings organized at which both old and new fine wines can be publicly sampled and evaluated, and also the possibility of visits to famous French Chateaus (e.g., Chateau Mouton-Rothschild or Chateau Margaux in Bordeaux) undertaken as a form of secular worship at the elaborate cathedrals of fine wine. As it can be argued that fine wine is consumed both for status and pleasure in equal measure, it might be suggested that the exhibition of status can also be a form of pleasure.

Conclusion

It can be highlighted that conspicuous consumption is not only a feature of individual behavior but of some types of group behavior as well. For example, organizations such as private companies may employ conspicuous consumption (e.g., the ownership of expensive large office buildings in very desirable locations) in order to advertise their company's business success. These buildings may also be used as part of an overall branding strategy.

Perhaps the most famous example of this company branding strategy is that of the former *The*

Apprentice host Donald Trump, with his brash Trump Tower and his extensive portfolio of other properties found at various prestigious locations around the world. The Trump Presidency can, from this perspective, be seen as the ultimate global branding opportunity – the White House as a new Trump Tower located at 1600 Pennsylvania Avenue, Washington, D.C. – serving as the crown exhibit of the entire Trump brand.

It is also worth pointing out that in more recent times, there has been a rise in the prevalence of inconspicuous consumption and/or ordinary consumption, as the very wealthy may sometimes prefer to remain to some degree anonymous, rather than to advertise their wealth to everyone and anyone (Gronow and Warde 2001). Too much conspicuous consumption may serve to attract thieves and loafers wanting to obtain their own personal slice of the wealthy lifestyle through illegitimate means.

Definition

George Williams was a highly influential evolutionary biologist best known for criticizing group-level selection and advocating in its place a focus on individual-level selection and adaptation.

Introduction

George Christopher Williams (1926–2010) was a highly influential evolutionary biologist best known for his contributions to understanding the evolution of senescence, to criticizing group-level selection and advocating individual-level selection and adaptation, and along with Randolph Nesse to establishing the field of evolutionary medicine. Williams was a professor in the Department of Ecology and Evolution in the State University of New York at Stony Brook.

Theory of Senescence

In 1957, Williams published *Pleiotropy, Natural Selection, and the Evolution of Senescence* – perhaps the most influential paper on the evolution of aging ever published. In it Williams made the argument that natural selection should result in aging because the force of selection is stronger earlier in life than later, and therefore selection would favor genes that have beneficial effects early in life even if they have detrimental effects later in life. His theory was thus based on pleiotropy – when single genes have multiple effects. His theory is often called the *antagonistic pleiotropy theory of senescence*. Peter B. Medawar had briefly mentioned the possibility of such pleiotropic genes resulting in aging in 1952, but Williams substantially developed the idea into a coherent explanation. In addition to antagonistic pleiotropy, the other core idea of Williams's theory was that natural selection tends to be stronger earlier in life than later in life. That the force of selection depends on age had first been recognized by one of the founders of modern evolutionary theory, Ronald A. Fisher, in 1930. Its underlying mathematics were elucidated by William D. Hamilton in 1966 in a paper whose focus was further elaborating Williams's argument that aging should result from age-dependent forces of natural selection. Subsequent research has largely supported Williams's theory, and to this day it is the leading explanation for the evolution of aging (another complementary and generally accepted theory, proposed by Medawar in 1952, is that harmful mutations expressed late in life should build up in a population because natural selection is weak or nonexistent at sufficiently advanced ages).

Group-Level Versus Individual-Level Selection and Adaptation

In 1966, evolutionary biologists often used group-level selection as their explanation of observed phenomena. In that year, Williams

published his most influential work, *Adaptation and Natural Selection: A Critique of Some Current Evolutionary Thought*. The book intended to “purge biology of . . . unnecessary distractions” (p. 4) and it soundly criticized using group-level and species-level selection as biological explanations, going so far as to say that “There is no respectable evidence of mechanisms” for such selection (p. viii). Many pages of this book summarize examples of biological phenomenon that were explained by others as due to group-level selection – for which Williams provides more parsimonious explanations using individual-level selection. This book was an early example of the shift in biological thinking in which evolution is seen from the gene level (an idea more fully developed by Richard Dawkins in his 1976 book, *The Selfish Gene*). Williams also clarified how biologists should use the idea of *adaptation*. For example, he argued that “Adaptation is a special and onerous concept that should not be used unnecessarily,” that “adaptation should be attributed to no higher a level of organization than is demanded by the evidence,” and that “Natural selection is the only acceptable explanation for the genesis and maintenance of adaptation” (p. vii). The emphasis that Williams placed on adaptations and the clarifications he made regarding them were influential in the historical development of what has been called the adaptationist perspective – a focus on adaptations as the key product of natural selection. The adaptationist perspective is arguably the foundational principle of evolutionary psychology (see, e.g., Barkow et al. 1992).

Notably, in 1992 Williams published a book in which he argued that although individual-level selection is the proper explanation for adaptations, it is insufficient as an explanation for which species exist on earth at any time – its biota. The explanation for the evolution of the biota, Williams argued, included that species and populations differ regarding their fitness as a group and so when considering macroevolution – the evolution of species and populations – group-level selection and multilevel selection can be important (along with chance events such as catastrophes).

Evolutionary Medicine

Williams, along with Randolph Nesse, published a paper (Williams and Nesse 1991) and then a book, *Why We Get Sick: The New Science of Darwinian Medicine* (Nesse and Williams 1994), that brought substantial prominence and recognition to the incipient field of evolutionary medicine (also known as Darwinian medicine). In their work, Williams and Nesse argue that medicine focuses on proximal causes of symptoms and so address what they see as a lack of awareness of the importance to understanding medical issues of the evolutionary (ultimate) perspective. Among six evolutionary explanations for diseases, they showed, for example, how some symptoms of illness – such as fever and iron deficiency – that are often thought harmful are instead part of the evolved human defense against pathogens. In addition to defenses, they addressed other aspects of medicine for which evolutionary theory would be expected to provide insights. Toxins damage tissue and cause birth defects, so pregnancy sickness suffered by human women today can be explained as a result of an adaptation for avoiding toxins in ancestral times. Some genetic diseases are likely the result of evolutionary selection for other effects of the same genes that are beneficial – especially early in life. Humans evolved in a stone-age world but live in a modern environment, and so mismatches of the modern world with our evolved biology and psychology might result in disease, as exemplified by excessive consumption of salt, fat, and other nutrients that were previously scarce. Williams and Nesse proposed that medical doctors should receive training in evolutionary approaches to the body and diseases, such approaches should be integrated into medical textbooks, and that evolutionary medicine be instantiated in departments, programs, and research institutes.

Conclusion

George Williams was a deep-thinking and far-sighted scholar who helped reign in unwarranted group-level explanations of

adaptations, refocused the attention of biologists and psychologists on the importance of adaptations and of selection at the individual and gene levels, and paved the way for a coherent approach to understanding medical issues from an evolutionary perspective.

Definition

George C. Williams was an evolutionary biologist with a specialty in ichthyology, best known for his book, *Adaptation and Natural Selection*, published in 1966, in which he asserted that the concept of evolutionary adaptation should be restricted to cases in which the demographic and population genetic evidence clearly supports the idea that a trait is the result of differential reproductive success. He also provided a strong argument against the concept of group selection and in favor of the classical Darwinian concept of individual selection. He also proposed that William D. Hamilton's newly proposed concept of kin selection could provide a testable explanation for the phenomena formerly explained by group selection.

Introduction

In 1962, V. C. Wynne-Edwards' book, *Animal Dispersion in Relation to Social Behavior*, was published in England by Oliver and Boyd (Wynne-Edwards 1962). It contained the most comprehensive analysis of animal social behavior published up to that time. Wynne-Edwards was an ornithologist, with a special focus on seabirds, which he cited as many examples in his *magnum opus*. Wynne-Edwards argued that many (perhaps most) social behaviors – everything from communication to socially induced mortality to territoriality – could be explained as evolutionary adaptations, the underlying effect of which would be the reduction of individual reproductive success within social groups. Such a reduction would have the effect of reducing ecological disruption to the environment of such social groups, thereby resulting in the increased survival of such groups relative to groups in which individuals maximize their reproductive success.

Main Idea

By 1962, George Williams had already published a landmark paper in evolutionary biology, "Pleiotropy, natural selection, and the evolution of senescence," (Williams 1957). In it he argued that a gene with pleiotropic effects – that is, a gene affecting more than one phenotypic trait – could produce antagonistic effects. One of the effects might result in increased reproductive success, while another effect of the same gene could result in decreased reproductive success. Williams proposed that any gene that resulted in early reproductive success would be selected for, even if it resulted in early senescence following reproduction. Such a gene would essentially result in individuals that "lived fast, loved hard, and left more offspring," and then died at a relatively young age as the result of degenerative conditions brought about by their "fast" early lives.

This idea – that adaptation is ultimately the result of differential reproductive success best attributed to natural selection at the level of genes – was central to Williams' most influential

work, *Adaptation and Natural Selection: A Critique of Some Current Evolutionary Thought*, published in 1966 (Williams 1966). Williams wrote it at least partly in response to Wynne-Edwards' earlier work. In it, Williams presented three interrelated arguments:

1. That the concept of evolutionary adaptation should be restricted to cases in which the demographic and population genetic evidence clearly supports the idea that a trait is the result of differential reproductive success
2. That the concept of group selection as proposed by Wynne-Edwards and others was unstable, as groups of individuals who reduced their reproductive success by whatever means could always be invaded and out-competed by individuals who maximized their reproductive success
3. That William D. Hamilton's newly proposed theory of kin selection (i.e., selection at the level of genes, rather than individuals or groups) could best explain the evolution of social behaviors, especially those that appeared to be altruistic

Williams first pointed out that far too many evolutionary biologists assumed that many (or even most) of the characteristics of animals qualify as evolutionary adaptations. He pointed out that the common assumption that a characteristic is an adaptation simply by virtue of its existence is a fallacy. Citing Darwin, Williams asserted that the concept of adaptation should be considered to be "... a special and onerous concept that should only be used where it is really necessary" (Williams 1966). He argued that only when a characteristic (i.e., a "trait") could be empirically shown to be the result of differential survival and reproduction and that this could be tied directly to a gene or genes producing that characteristic, should it be considered to be an evolutionary adaptation.

Williams' emphasis on natural selection being best analyzed at the level of genes is squarely in the tradition of the "modern evolutionary synthesis," as formulated by R. A. Fisher, J. B. S. Haldane, and Sewall Wright and

elaborated by Theodosius Dobzhansky and Ernst Mayr. The “modern synthesis” had its roots in the Hardy-Weinberg equilibrium law, first proposed in 1908 by British mathematician G. H. Hardy and German physician Wilhelm Weinberg. According to the Hardy-Weinberg law, there will be no change in allele frequencies in a population if four conditions are met: (1) no net mutation, (2) no net gene flow, (3) an effectively infinite population, and (4) random survival and reproduction. This law was based on the assumption that natural selection ultimately operates at the level of genes (i.e., alleles, alternate versions of genes), which produce the characteristics of organisms that result in their relative survival and reproductive success.

This idea – that evolution by natural selection ultimately happens at the level of genes – was central to the “modern evolutionary synthesis.” W. D. Hamilton’s (Hamilton, 1964) concept of kin selection was based on this same underlying idea that social behaviors, and especially altruism, could be explained by differential survival and reproduction of genes, with individual animals serving simply as their vehicles. This idea of the “selfish gene,” usually attributed to Richard Dawkins, has its roots in George Williams’ critique of Wynne-Edwards’ concept of group selection. Williams argued that virtually any group of individuals who collectively reduced their reproductive output could be invaded and ultimately replaced by individuals who maximized their reproductive output.

Consider a population of social animals – say birds in a forest. There are only enough resources available in the forest to support a limited number of birds. According to Wynne-Edwards’ theory of group selection, a group in which all of the individuals limit their reproductive output by whatever means (courtship and dominance displays, territoriality, etc.) would be more likely to survive than a group composed of individuals that maximized their reproductive output because the self-limiting group would be less likely to exceed the carrying capacity of their environment.

However, what would happen if individuals that did not limit their reproductive output entered such a group, either by immigration or mutation

(i.e., of a gene or genes that regulated their reproductive behavior)? In a fairly short time, such “selfish” individuals would outnumber their “altruistic” cohorts and would eventually replace them. In essence, altruistic individuals that restrict their reproductive output should always eventually be replaced by individuals that maximize their reproductive output. The only conditions under which this would not happen would be in highly circumscribed, very limited ecosystems in which the individuals are relatively genetically homogeneous, conditions rarely if ever met in nature.

This argument is similar to Garret Hardin’s concept of the “lifeboat ethics.” Imagine a lifeboat adrift in cold water following the sinking of a ship (e.g., the *Titanic*). There are two “types” of people in the lifeboat and in the surrounding water. One type are “altruists,” who will give up their places in the lifeboat to anyone in the surrounding water. The other type are “selfish” individuals who will either not give up their places in the lifeboat or will climb into the lifeboat from the water. The result of the interactions between these two types of individuals will inevitably be a lifeboat full of “selfish” individuals and the surrounding water full of “altruists,” who will eventually die of hypothermia (Hardin 1974).

In *Adaptation and Natural Selection*, George Williams argued for an alternative explanation for the evolution of social behavior and altruism: the theory of kin selection, proposed by British population geneticist and evolutionary biologist William D. Hamilton. According to Hamilton’s rule, behaviors that benefit others at some cost to the individual performing the behavior can evolve (i.e., be selected for) if the individual (s) receiving the benefit is closely genetically related to the individual performing the behavior. Algebraically, Hamilton’s rule is

$$C < r \times B$$

where C = the cost to the individual performing the behavior, r = the coefficient of relationship between the individual performing the behavior and the individual receiving the benefit, and B = the benefit to the individual receiving the benefit. This means that the more closely related two individuals are, the greater the benefit

to the altruist's genes that are shared with the recipient of their altruism.

Again, this idea is squarely in line with the underlying basis of the "modern evolutionary synthesis," that natural selection happens at the level of genes, not individuals or (especially) groups. What ultimately matters is not whether the individual performing any particular social behavior survives or reproduces, but rather whether the genes carried by that individual increase or decrease in frequency in the population as the result of the behavior. If the answer is yes, then the tendency to perform such behaviors can increase in frequency even if the individuals performing them survive and/or reproduce less often than the recipients of their altruism.

Williams' arguments in *Adaptation and Natural Selection* were extraordinarily influential among evolutionary biologists, especially in the United States and the United Kingdom. The concept of group selection was considered to have been thoroughly debunked and theories explaining the evolution of social behaviors based on kin selection were accepted in their place. In the years following its publication, and the publication of Hamilton's papers on kin selection, field and laboratory research testing these new theories accelerated dramatically. There were many successes, as empirical research supported the new paradigm and suggested further applications of the theories and their underlying concepts.

Another landmark in the development of evolutionary theory following Williams' publication of *Adaptation and Natural Selection* was Robert Trivers' publication of "The evolution of reciprocal altruism" in 1971 (Trivers, 1971). Trivers pointed out that not all cases of apparently altruistic behavior could be explained by kin selection. In particular, close social cooperation between completely unrelated individuals, such as cleaner fish and their hosts and warning calls in mixed species flocks of birds, occurs between individuals of different species. Trivers presented a theory based on reciprocal altruism: individuals will cooperate with other individuals if the cost they incur by doing so is offset by a related benefit they receive as the result of reciprocation of that

behavior. According to Trivers' theory, six conditions must be met for reciprocal altruism to evolve:

1. Interactions between potential reciprocal altruists must be repeated multiple times.
2. The cost to the individual performing a single altruistic act must be relatively small, especially at first.
3. The recipient of an altruistic act must eventually reciprocate the altruistic act to the individual that performed it for them.
4. Individuals participating in reciprocal altruism must be able to recognize specific individuals and remember the outcome of their previous interaction(s).
5. Individuals must be able to recognize non-reciprocators (i.e., "cheaters") and retaliate.
6. There should be no definite end point to the interactions between individuals.

If these conditions are met, cooperation between reciprocating individuals can evolve and increase indefinitely.

Triver's theory of reciprocal altruism was extended by W. D. Hamilton and Robert Axelrod in 1981, with the publication of *The Evolution of Cooperation* (Axelrod and Hamilton 1981). Axelrod and Hamilton organized a computer tournament in which mathematical game theorists could submit programs that would compete to see which behavioral strategy had the highest "fitness" (defined as obtaining the largest relative quantity of benefits from an altruist). The default strategy was pure selfishness, which was pitted against all of the submitted programs by Axelrod and Hamilton. The program that won was submitted by game theorist Anatol Rapaport. Called "tit for tat," this program was simple: cooperate during the first interaction and then do exactly what one's opponent/partner does in response. If the other player "defected" (i.e., was "selfish"), then the first player would be selfish until the other player cooperated (if ever). "Tit for tat" not only won, it was able to invade and eventually replace a population of purely selfish individuals, as long as there was at least one other altruist in the group.

The rapid development of the application of evolutionary theory to social behavior following Williams' publication of *Adaptation and Natural Selection* led to the founding of a new field of evolutionary biology. In 1975, Harvard evolutionary biologist E. O. Wilson published *Sociobiology: The New Synthesis* (Wilson, 1975). In it he drew together all of the various threads of theoretical evolutionary biology, natural history, anthropology, and psychology in a comprehensive analysis of the evolution of social behavior through the animal kingdom. Wilson divided *sociobiology* into four main sections: a historical outline of the development of the field, a presentation of the major theoretical components of the discipline, a phylogenetic review of the various social species of animals (organized into four subsections: the colonial invertebrates, the social insects, the social vertebrates, and primates), followed by an extended analysis of human social behavior.

Like most of the work upon which it was based, Wilson's sociobiology was ultimately grounded in the concepts of evolution by natural selection at the level of genes. Wilson, like Williams, argued that ultimately all evolutionary adaptations could be explained by differential survival and reproduction of particular genes, which in turn produce the phenotypic characteristics that allow the carriers of those genes to survive and reproduce. For most evolutionary biologists, this extension was not controversial, as the idea that evolution by natural selection ultimately happened at the level of genes was a founding concept of the "modern evolutionary synthesis."

However, these ideas were very controversial in the social sciences. Wilson was accused by some social scientists of reviving a kind of "scientific social Darwinism." Wilson was attacked, both in the press and in person, and the concepts of sociobiology were vilified, even when applied to nonhumans. So intense and prolonged was this controversy that eventually the term "sociobiology" became a negative epithet, and evolutionary biologists who pursued it were vilified and their work attacked.

In time, this resulted in the coining of a new term for the application of evolutionary theory to

the understanding of human behavior. This new field, evolutionary psychology, is one of the fastest growing and controversial disciplines within evolutionary biology and psychology. However, unlike sociobiology, evolutionary psychology does not necessarily reject natural selection at the level of individuals nor even at the level of groups.

This is most noticeable among those evolutionary psychologists who base at least some of their ideas on the theoretical work of George R. Price, an American mathematician, physical chemist, and population geneticist. Price did virtually all of his work alone, outside of established academic circles. Largely self-taught, Price re-derived Hamilton's theory of kin selection using a mathematical model that has become known as the Price equation (Price, 1970). Based on a mathematical process called covariance, the Price equation provides a theoretical mechanism by which a group can increase in fitness relative to another group because of the presence of altruistic individuals within the group. According to the Price equation, groups that include altruists can increase in fitness relative to groups without altruists, even if the relative proportion of altruists within such groups decreases over time. Under such conditions, the absolute number of altruists in the successful group can be larger than the absolute number of individuals in a competing group lacking altruists. Therefore, altruists have higher fitness when compared with non-altruists in competing groups, even though they have lower fitness within their groups.

Once again, the Price equation is ultimately founded on the theoretical basis of the "modern evolutionary synthesis," that evolution by natural selection happens at the level of genes. This idea also conforms to George Williams' caveat about the restricted applicability of the concept of adaptation. Applying the Price equation to real populations fulfills Williams' requirement that calling a phenomenon an adaptation be grounded in measuring fitness by measuring survival and reproduction, albeit at the level of genes rather than individuals.

George Williams counselled evolutionary biologists to avoid explanations based on group

selection. However, one of the paradoxes of modern evolutionary theory is that by applying Williams' strictures to actual populations – that is, by requiring that any analysis of fitness be grounded in differential survival and reproduction – it is now possible to derive a mechanism of natural selection that can be shown to happen at the level of groups, in addition to the level of individuals and the level of genes. This idea, called multi-level selection, has been most vigorously promoted by David Sloan Wilson of Binghamton University. Wilson has used group selection theory based on the Price equation to explain group social behavior in such disparate groups of animals as chickens and humans. In *Unto Others: The Evolution and Psychology of Unselfish Behavior* (co-edited with Elliot Sober) (Wilson & Sober, 1998), Wilson and Sober explored how human social behavior can evolve via group selection as well as individual selection. They concluded that altruism – defined as behavior that benefits other individuals without benefiting one's shared genes or requiring reciprocation – can evolve by natural selection.

Conclusion

George C. Williams' influence on evolutionary biology has been and continues to be profound and long-lasting. His debunking of Wynne-Edwards non-quantitative idea of group selection and its replacement with Hamilton's quantitative theory of kin selection ultimately led to the founding of sociobiology, a new field within evolutionary biology. Sociobiology, in turn, gave rise to the new and rapidly growing field of evolutionary psychology. Paradoxically, this has resulted in the quantitative reformulation of group selection theory and its application to human social behavior.

Williams' exhortations to evolutionary biologists to use the term "adaptation" parsimoniously have also resulted in an increased emphasis on three qualities in evolutionary research: reliability, efficiency, and economy. Evolutionary explanations that are grounded in quantitative analysis are ultimately more reliable than qualitative

explanations. Quantitative explanations can be empirically tested and either validated or falsified. This has resulted in greatly increased efficiency in field and laboratory research in evolutionary biology, as investigators can much more easily decide which explanations are more likely to reflect biological reality. Finally, Williams' emphasis on quantitative explanations accords with one of the foundational principles of all of the natural sciences: the concept of parsimony, often referred to as Occam's razor. Evolutionary explanations based on quantitative analyses are more parsimonious – they require fewer assumptions and produce much more straightforward and unambiguous results and interpretations than more qualitative explanations. As such, the theories of evolutionary biology that have themselves evolved from George Williams' exhortations have resulted in a body of knowledge that is simultaneously more economical and more comprehensive. The field of evolutionary psychology owes a great debt to his work and can continue to benefit from following his advice.

George Williams on Group Selection

Definition

In the study of adaptation, George Williams makes clear that group selection is not a valid explanation for traits developed by individual organisms. In his book *Adaptation and Natural Selection* (1966), he outlines some previous claims concerning the validity of group selection and discusses how they are frequently inadequate to explain the adaptation and evolution of species. There are several theories to which he gives some merit, but only in special cases that are not common in nature.

Introduction

Group selection, to George Williams, is frequently not a plausible explanation for the way that

individual organisms develop adaptations that enable them to survive in their respective environments. While he concedes that there are a select few group selection theories that have merit, he largely considers the approach to be misguided. While it often might seem that a population has evolved, Williams (1966) argues that in actuality the survival of the population is due to adaptations in the individuals that comprise it. The population itself has not involved per se but is comprised of adapted individuals.

A point Williams (1966) makes early in his book, *Adaptation and Natural Selection*, to support his claims is that the difference between phenotype and genotype expression is key to understanding how group adaptations can appear to occur. Whereas it is possible for an individual's environment to affect the way that a genotype is expressed through a phenotype, that environment does not truly alter the genotype. The phenotypic expression of a gene can differ between individuals, but the underlying genotype remains the same. Thus, while environmental pressures can alter phenotypic expression, they do not affect an actual genetic change within members of the population.

Probable Cases of Group Selection

Williams gives some consideration to Wright's (1945) theory that group selection functions in populations that are divided into several smaller populations. Wright argued that in a population divided into smaller populations, group selection would be most effective, as movement of individuals between the populations would alter the group genes and correct adverse selection and create a stronger species overall. In order for this type of population to exist and evolve in such a way, however, the populations would have to be of a very specific size and with a very specific immigration rate, which would both be difficult to occur by chance in nature.

The only theory of group selection that Williams truly admits has merit is that of Lewontin (1962) and Lewontin and Dunn (1960). In his studies of a species of house mice, he found what Williams considers to be one of the only

plausible cases of group selection. In the species, there exists a gene that produces a segregation distortion in sperm that creates a strong selective advantage for a certain gene. When studying wild populations, however, this gene, though it should be selected for, appears at a much lower frequency than would be expected in a deterministic model of selection. It was thus concluded by Lewontin and accepted by Williams that in this specific case, group selection within small populations and familial groups might be what causes the discrepancy in gene frequencies. This type of population, however, where lethality and sterility are to blame for the segregation distortion, is very rare, and Williams therefore would not generalize the type of group selection observed within the house mice to other species.

Conclusion

Overall, Williams maintains that group selection is very rarely the process that is driving the adaptation of organisms. The point of advantageous adaptations, he argues, is to keep the individual alive and able to reproduce; there is no mechanism that drives adaptations that favor the survival of the group. This is not to say that the group will not benefit from the adaptation of individuals – in many cases, a group of adapted individuals will experience increased fitness – but this benefit is only a fortunate side effect of individual adaptation.

Definitions

Gestalt is a German word that roughly translates to shape or form. Gestalt Theory attempts to define the fundamental rules of how individuals perceive stimuli in the environment as a complete form, rather than a group of smaller disconnected parts. A Gestalt is a complete percept that arises from the integration of small individual parts of a whole. This “whole” is not simply a sum of its parts, but becomes something more (Wagemans

et al. 2012a). The whole becomes something else entirely; something that has a greater significance (Koffka 1935).

Introduction

Gestalt theory is a theoretical standpoint in perceptual psychology that emerged from the work of Max Wertheimer's 1912 paper on the phi phenomenon, or apparent motion (Wertheimer 2014). Apparent motion is the illusion that results when researchers present two stationary visual stimuli successively and create the percept that one object has moved through space. In other words, the whole becomes completely different than any sum of its parts; it becomes a Gestalt. This discovery led to a cascade of scientific experiments examining the laws that govern how the brain stitches the world together. Most researchers consider Max Wertheimer to be the father of Gestalt theory, which took a fundamentally different approach to the mind than the Structuralist point of view. However, Wertheimer was by no means the only researcher examining the science of perception. Wolfgang Kohler and Kurt Koffka are both prominent researchers that helped to expand and disseminate the core ideas that would become the organizational principles of perceptual psychology (Wertheimer 2000).

Gestalt Organization

Gestalt organization refers to the ways in which the perceptual system organizes the world into meaningful wholes. There are several distinct categories of Gestalt organization. First, there are Gestalt grouping principles, which are the most well-known of the organizational laws. Gestalt grouping principles refer to the way that the brain interprets percepts as together or apart. Gestalt organization also includes figure-ground organization. Figure-ground organization refers to the ways in which the perceptual systems organize objects into a three-dimensional world based on their properties. Finally, contour integration also falls under the label of organizational principles.

Contour integration refers to the diverse ways that contours affect how we perceive different aspects of the environment (Wagemans et al. 2012b).

Gestalt Grouping Principles

Gestalt grouping principles examine the relational qualities of percepts and how those qualities lead to specific groupings (see Fig. 1). Some of the most common Gestalt grouping principles are the principles of proximity, similarity, common fate, symmetry, parallelism, continuity, closure, common region, and connectedness (Wagemans et al. 2012b). Some of these principles are easier to illustrate using simple geometric shapes, while others can be more difficult.

The principles of proximity, similarity, and common fate are some of the easier principle to illustrate. The principle of proximity was the first of Wertheimer's principles of grouping and referred to the ways that objects group together. Specifically, objects, like dots, group together based on their relative distance from one another. When the dots are equidistant from one another, the perceptual system does not see them as being part of the same group. However, when the space decreases between every other dot, the brain perceives each pair of dots as an individual group, separate from the rest. Another primary principle of Gestalt grouping is the principle of similarity. The principle of similarity states that the perceptual system groups together objects that are similar. Similarity can refer to the color, size, shape, and about any other set of characteristics one could think of. A third major principle of Gestalt grouping is the principle of common fate. The principle of common fate states that the perceptual system groups items that move in the same way. More recently, research by Sekuler and Bennett (2001) has illustrated that the principle of common fate can apply to more widespread characteristics than just movement, like luminance changes.

Other principles of Gestalt grouping apply less to general objects, like dots, than to qualities and features, like lines and areas. For example, the principles of symmetry and parallelism tend to

Gestalt Theory, Fig. 1 Principles of Gestalt grouping. *No Grouping*: how objects appear when there are no grouping principles at work. *Proximity*: objects group together when they are closer together. *Similarity*: similar items group together. Both the *black* and *gray squares* form their own groups. *Common Fate*: items that are moving in similar directions group together (the *arrows* represent vectors of motion). *Continuity*: two lines that cross over each other in the middle of each line will result in observing two lines passing through one another, rather than two

opposing angles. *Closure*: items that form closed objects will group together. *The Kanisza triangle*: illusory contours can create a recognizable image (e.g., triangle), despite having no actual contours. *Figure-Ground Reversal*: the figure and ground of an image can shift based on the observers focus. If the observer looks at this figure with the *black* area as the image, a chalice will appear. However, if the observer focuses on the *white* area as the image, two faces appear looking towards one another

form groups with items that are either symmetrical or parallel. The principle of continuity states that two lines that intersect in the middle of each length will appear as lines that continue to go through one another, rather than forming two opposing angles. In other words, the perceptual system parses an “X” as two lines passing through one other rather than two obtuse angles meeting at their vertices. The principle of closure states that the perceptual system will group items together when they create a closed object. The principle of closure is a powerful grouping principle that it tends to overwhelm that of continuity (Wageman 2012b).

An additional area of Gestalt grouping are principles that relate to global spatial relationships. These are the principles of common region and connectedness. The principle of common region states that the perceptual system interprets objects confined to a common spatial area as being a part of the same group. For example, when looking at a face, one understands that the eyes and nose belong to the same face. Connectedness refers to the fact that the perceptual systems describe connected items as part of the same group. That is not to say that the principle of connectedness is the same as the principle of proximity, as proximity does not account for

objects behaving together (Palmer and Rock 1994).

Figure-Ground Organization

Figure-ground organization refers to the way that percepts in the environment separate from one another in three-dimensional space, some objects becoming figures and others becoming the ground. Specifically, how the perceptual system organizes figure-grounds relies upon several parameters, like motion and previous experience.

The major figure-ground organizational phenomena are convexity and symmetry, but there are many others. Convexity refers to the way in which convex items appear as figure items about 90% of the time (Wageman 2012b). Symmetry refers to the organizational principle that symmetrical items are more often seen as being figures, while asymmetrical areas tend to be the ground or background. Other forms of figure-ground segregation also exist in the form of top-bottom polarity, edge-region grouping, and motion. Top-bottom polarity refers to the way objects that have a wider base and a thinner top appear as if they are the figure in an image. Edge-region grouping refers to the way Gestalt grouping principles effect the perception of where figures belong in a three-dimensional space. Motion can be a major cue to figure-ground separation as well. The visual system interprets the motion of borders that appear to grow as the figure overtaking the ground. Also, when contours change dynamically, observers tend to assign the concave surface to the figure rather than the ground (Barenholtz and Feldman 2006). Some figures can have figure-ground reversals, such as the face-chalice image (see Fig. 1).

Illusory Contours

Contour integration and perception also make use of Gestalt grouping principles. Principles like continuity, closure, proximity, and similarity all work together to help with the perception of contours. These grouping principles can even create

illusory contours where none exist, like in the Kanisza triangle (see Fig. 1). Though no contours are present, the observer perceives the presences of a triangle due to the powerful grouping principles of closure and continuity.

Conclusions

The brain faces the complex task of making sense of an ever-changing world every second of every day. The sheer amount of detail that exists even in a small fragment of time is beyond even the capability of the attentional system of the brain to understand. Yet, each of those fragments of time consists of moments filled with recognizable and describable items that the brain interprets. The brain interprets these items as “whole” objects, not as lines and edges undefined in space. Gestalt theory describes the laws that create the “whole.” In essence, Gestalt theory is the study of how we experience the world.

Gestational Diabetes and Maternal-Fetal Conflict

Definition

A condition in which previously nondiabetic women develop insulin resistance and high blood glucose levels during pregnancy. Typically occurs late in pregnancy (third trimester) and usually resolves shortly after delivery.

Introduction

Evolutionary conflict occurs when natural selection acts in opposing directions on different genes involved in an interaction (Burt and Trivers 2008). The conflict can be found at all levels of organization, from conflict between species, to conflict between individuals within a species, to conflict within an individual itself. Most of these forms of conflicts revolve around competition for resources and differences in optimal resource allocation among individuals. Between genetic relatives, what is beneficial to one relative may not be beneficial, and may even be detrimental, to another. This situation occurs when there is an unequal probability that genes from one individual will be shared with another. For example, if a mother invests abundant resources in one fetus, it benefits both that fetus and, due to shared genes, the mother herself; however it will detract from the mother's ability to invest in other offspring. From the maternal perspective, she shares half her genes with each of her children, so she benefits optimally from maximizing her reproductive output. However, from the perspective of any one child, there is a lower probability that a gene found in that child's genome will be present in other siblings (although there is a 50 % probability that a maternal gene found in one sibling will be found in the other, the sibs may not be paternally related, thereby reducing their probability of genetic similarity) (Trivers 1974). Therefore there is an unequal benefit for the child relative to the mother when she allocates resources to any one child versus conserving resources for other potential offspring. These situations produce what is known as maternal-offspring conflict.

Just as siblings bicker over who gets the biggest piece of cake, so too there is competition over

metabolic resources in the womb. While mom wants healthy offspring, it is in her best interest to limit the resources given to each child, so that she will be able to conserve her resources for future reproductive outputs. However, the paternally inherited genes found in the baby benefit from extracting as many resources from the mom as possible, with less concern for her future reproductive success. One way in which this materializes is over regulation of maternal blood glucose.

What is Gestational Diabetes?

Pregnancy results in a variety of metabolic changes, including increased blood glucose and decreased insulin activation. These are necessary to accommodate high and rising fetal energy demands. However, gestational diabetes (GD) refers to a condition wherein maternal blood glucose levels are abnormally high, usually during the second or third trimester (Di Cianni et al. 2003). This can result from inadequate insulin levels or increased insulin resistance, whereby the glucose is not being absorbed by cells in response to increased insulin concentration. Evolutionary theory can help us understand why GD is so common, affecting approximately 9.2 % of American mothers in 2010 (DeSisto et al. 2014) and up to 20 % of pregnancies in other cultures (Brown et al. 2013).

While fasting blood sugar levels fall early in gestation, they appear to stabilize at a lower baseline from the 12th week of pregnancy until delivery. By contrast, maternal insulin levels remain quite stable until the last trimester, at which time they increase to meet the rising metabolic demands of the growing fetus (Haig 1993). However, during this time maternal responsiveness to insulin's effects is decreasing. While this may seem odd, these phenomena can be explained through the lens of genetic conflict. Evolutionary predictions are as follows: (1) fetal glucose demands will be larger than the maternal optimum; (2) maternal countermeasures should

be in place to limit fetal access (Haig 1993). There is indeed evidence for both of these hypotheses.

Prediction 1: Fetal Glucose Demand

To address the first prediction, compare the rate of glucose consumption by the placenta relative to glucose concentrations in maternal blood. The placental glucose transport system has excess capacity, meaning that the placenta can continue to transport glucose to the fetus at a rate proportional to the glucose available in maternal blood, even when that is well above the normal physiologic range (Desoye et al. 2011; Hauguel et al. 1986; Ingermann 1987). In fact, the placenta is able to store excess glucose in the form of glycogen for later fetal transport (Desoye et al. 2011). In the case of GD, where the maternal blood glucose levels are extremely high, this often results in fetal complications, including macrosomia (high birth weight for gestational age) (Di Cianni et al. 2003). Furthermore, placental hormones block the ability of the maternal body to utilize insulin (conferring insulin resistance), and the placenta contains enzymes for rapid insulin degradation (Haig 1993). In fact, late in pregnancy maternal insulin action is 50–70 % lower than in nonpregnant controls (Butte 2000). This demonstrates a reduced efficacy of insulin in reducing glucose in the maternal blood stream, thereby increasing the amount of time glucose is available to the developing fetus.

Prediction 2: Maternal Countermeasures

To examine the second prediction, look into maternal insulin production. Early in pregnancy, when fetal glucose demands are still quite low, maternal fasting blood glucose levels fall and appear to restabilize at a lower level (Haig 1993). This has been interpreted as a “resetting” of maternal homeostasis in preparation for increased fetal demands (Haig 1993). By contrast, maternal insulin levels remain low early in

pregnancy but increase as fetal glucose demands rise. However, while more maternal insulin is being produced, it becomes less and less effective at reducing maternal blood sugar levels; the increase in maternal insulin production appears to be a competitive compensatory response to its decreased efficacy (Haig 1993). Furthermore, there is evidence that maternal insulin production spikes by about 120 % immediately after glucose intake, while the longer-term effects (5–60 min after intake) remain the same as in nonpregnant controls (Butte 2000). The longer the mom takes to reduce her available blood sugars, the more the fetus is able to extract. These results are consistent with the hypothesis of maternally evolved countermeasures to reduce placental glucose availability, as they demonstrate a timely maternal response.

Conclusion

While these fetal/maternal coadaptations work to produce healthy offspring in the majority of pregnancies, the modifications to the maternal glucose and insulin systems during pregnancy can trigger GD in some mothers. In a study of nondiabetic pregnancies, women whose blood glucose levels were higher within two hours after eating tended to give birth to heavier babies (Lorenzo et al. 1986); this indicates a direct benefit to the fetus at a cost to the mother, as women who show increased insulin resistance during pregnancy are more likely to develop diabetes later in life (DeSisto et al. 2014). Maternal response through decreased baseline blood sugar levels and increased insulin production later in pregnancy appears to be evolved countermeasures in response to increased fetal demands.

The gestural theory of language evolution states that the languages that humans speak today arose from an earlier form of communication that was expressed primarily through arm and hand gestures.

Introduction

According to the gestural theory of language evolution, our ancestors were able to communicate intentionally through gestures but could not control their vocalizations. Therefore, they primarily

used gestures to communicate purposefully; spoken language only began to emerge from this primarily gestural form of communication as our ancestors' ability to control their vocalizations increased.

Different gestural theories of language evolution have been proposed (e.g., Arbib et al. 2008; Corballis 2002; Hewes et al. 1973). Gestural theories of language evolution contrast with an opposing set of theories that assert that it is more parsimonious to assume that language evolved from simpler forms of primate *vocal* communication, such as song, because human language is now communicated primarily through vocalizations (e.g., Livingstone 1973). Current evidence suggests that gestural *and* vocal theories of language evolution are not incompatible. In fact, both may be more accurate when combined into a multimodal theory of language evolution, wherein human language evolved from, and continues to utilize, mutually informative gestures and vocalizations (e.g., Armstrong 2002; Masataka 2008).

The History of the Gestural Theory of Language Evolution

In 1973, Hewes published a paper wherein he synthesized then recent research about nonhuman primate communication to provide support for a gestural theory of language evolution. According to Hewes (1973) version of the gestural theory of language evolution, our ancestors communicated primarily through a language composed of arm and hand gestures; spoken speech only later replaced gestures as the dominant mode of human linguistic communication. Although his theory provided little detail about the process by which gestures came to be replaced by vocal speech, he speculated that our ancestors could have learned to speak by imitating animal noises as they began to hunt more frequently. Hewes emphasized that vocal communication in no way completely replaced gestures in modern languages as people still use gestures to add nuance and emphasis to their speech. He also stated that different aspects of modern culture are rooted in

gesture (e.g., painting) and vocal communication (e.g., poetry) respectively.

Hewes began his paper by providing a list of distinguished authors, beginning with Condillac in 1746, all of whom he believed had also promoted the idea that “man’s first language was primarily gestural” (Hewes et al. 1973, p. 65). He stated that the descriptions of the gestural theory of language evolution provided by earlier scholars were limited by their lack of access to then recent discoveries about primate communication. Key findings that Hewes used to support a gestural theory of language evolution included: (1) evidence that nonhuman primates (e.g., chimpanzees), who even after years of teaching cannot learn to express more than a few words through speech, can be taught to communicate effectively through sign language (e.g., Gardner and Gardner 1969), (2) anecdotal evidence that chimpanzees commonly communicate through gestures (e.g., Van Lawick-Goodall 1968), (3) evidence that nonhuman primates’ calls are involuntary emotional reactions that are emitted regardless of whether others are around to hear them (e.g., Bates 1970), (4) evidence that our ancestors could not produce certain sounds that are essential for modern human speech (i.e., the vowels [a], [i], and [u]) derived by reconstructing the vocal apparatus of ancient nonhuman apes from fossils (Lieberman et al. 1972), and (5) evidence that skilled motor movements, such as those required to use tools, and language are both primarily controlled by the left side of the brain (Lenneberg 1967a as cited by Hewes et al. 1973).

A number of subsequent researchers have extended upon Hewes’ work to provide further evidence for and alternative conceptualizations of a gestural theory of language (e.g., Arbib et al. 2008; Armstrong 2002; Bonvillian et al. 1997; Corballis 2009; Pollick and De Waal 2007; Skoyles 2000). For example, Bonvillian et al. (1997) described a study conducted over 400 years ago by Akbar, the then emperor of Hindustan, that revealed that infants reared by mute nurses never learned to speak and only communicated with gestures; they asserted that this study provided evidence for a gestural theory of language evolution.

Subsequent research has provided support for a number of the pieces of evidence that Hewes’ used to support his version of the gestural theory of language. For example, subsequent research has demonstrated that other apes (besides the chimpanzees who learned sign language with the Gardners), including orangutans and gorillas, also learned to communicate effectively through sign language but not through spoken language (e.g., Miles 1990; Patterson 1978). Subsequent research has also provided extensive support for his claim that nonhuman apes commonly communicate through gesture (e.g., Pollick and De Waal 2007; Roberts and Roberts 2016). In addition, striking commonalities between nonhuman and human primates have been observed in the types of gestures they use and the process by which their gestures often develop (i.e., during meaningful interactive routines; Bard et al. 2014; Gillespie-Lynch et al. 2014).

Subsequent studies have also supported Hewes’ assertion that the gestural communication of nonhuman primates is far *more* flexible than their vocal communication (e.g., Pollick and De Waal 2007). However, more recent research has *not* supported his assertion that apes are not able to control their vocalizations at all. Instead, research demonstrates that nonhuman primates adapt their vocalizations *and* their gestures to shifting social situations. For example, chimpanzees modify their vocalizations based on whether dominant individuals are present (Laporte and Zuberbühler 2010) and more often use gestures that make a noise which can be heard at a distance, like drumming, when they have a larger number of other apes who they are close with to stay in touch with (Roberts and Roberts 2016).

Subsequent research has also challenged Hewes’ assertion that our ancestors were incapable of producing human-like speech sounds by critiquing Lieberman and colleagues’ reconstruction of the vocal apparatus of a Neanderthal. For example, Falk (1975) asserted that the reconstruction was inaccurate because a key bone (the hyoid bone) was positioned too high in the larynx (the voice box) in the process of reconstruction; not only would an animal with such a high hyoid bone

not have been able to communicate through articulate speech, it also would not have been able to swallow. Indeed, a subsequent study utilizing the fossil of an ancestral ape with a complete hyoid bone revealed that the structure of the hyoid bone was remarkably similar to that of a modern human, which the researchers interpreted as evidence that ancestral apes were capable of producing modern speech sounds after all (Arensburg et al. 1990).

Subsequent researchers have extended upon Hewes' assertion that skilled motor movements and language are typically both supported by the left side of the brain by focusing on specific regions of the brain that support both language and skilled motor movements (e.g., the mirror neuron system) to develop their own adaptations of a gestural theory of language evolution. The mirror neuron system consists of neurons in different regions of the brain that respond when primates see others make a movement or when they do the same movement themselves. This system is believed to help primates understand one another's intentions and learn from one another.

Arbib et al. (2008) and Corballis (2009) both indicated that the presence of mirror neurons within a portion of Broca's area (an area in the prefrontal lobe of human brains that supports the production of both language and skilled movements) and its homologue (an area with a similar position and structure) in nonhuman primates provides evidence for their respective adaptations of a gestural theory of language evolution. Mirror neurons are distributed in many regions throughout the brain including a network of regions that support language (Fogassi and Ferrari 2007). Both Arbib and Corballis stated that mirror neurons could provide language learners, including our ancestors who were developing language, with the insights about the intentions and perspectives of those they were communicating with needed to produce and understand shared communication. Both researchers attempted to address a key gap in Hewes (1973) paper, specifically his lack of clarity about how gesture was eventually supplanted by vocal communication. However, they did so in different ways.

Arbib et al. (2008) asserted that the ability to imitate others that mirror neurons provide allowed our ancestors to learn to pantomime one another and that these early pantomimes developed into "protosign" or conventionalized gestures. He believed that "protosign" served as the foundation for "protospeech" or conventionalized vocalizations and that "protosign" and "protospeech" evolved together to become "protolanguage" (an early form of language which he believed to be multimodal). Although Arbib believed that language grew to be multimodal with time, he stated that gesture played the initial role in allowing our ancestors to develop language.

Corballis (2009) also focused his adaptation of the gestural theory of language evolution on the mirror neuron system. He also emphasized the support that recent evidence demonstrating that signed languages are as grammatically complex as spoken language provides for a gestural theory of language (Armstrong 2002). Unlike Arbib, Corballis did not believe that language *ever* transitioned from gesture into either a vocal or an explicitly multimodal mode of communication. Instead, he stated that modern "language, whether spoken or signed, can be viewed as a gestural system, evolving from the so-called mirror system in the primate brain" (p. 19). He supported his assertion that vocal language is a type of gesture by referring to the motor theory of speech perception. This theory states that our understanding of language is derived from how words are produced rather than the specific sounds produced (Liberman et al. 1967). Corballis stated that a gradual transition from manual gestures to increasing use of gestures of the face and mouth could have co-occurred with the increasing involvement of the hands in tool manufacture and use.

Further support for a gestural theory of language evolution has arisen from the field of developmental psychology. Infants typically learn to express concepts first through gestures (e.g., by pointing at a cat) before later expressing them through spoken speech (e.g., by saying the word "cat"; Capirci et al. 2005). A recent study evaluated if gesture supports the symbolic development of both human and nonhuman primates by

examining the gestural and symbolic development of language-enculturated (e.g., reared in language-enriched environments) primates possessing a common immediate ancestor (Gillespie-Lynch et al. 2014). Communicative behaviors observed among multiple species sharing a common ancestor are likely to have been present in the common ancestor. A chimpanzee, a bonobo, and a human child were reared in language-enriched environments and evaluated at comparable stages of communicative development. Similarities in the form and function of many gestures produced by the chimpanzee, bonobo, and human child suggest that gestural skills may indeed have contributed to linguistic development for our common ancestor. Indeed, a developmental transition from greater reliance on gesture to increased reliance on linguistic symbols was present for all three species though it was more pronounced for the child than the apes. However, multimodal expressions of communicative intent (e.g., pairing vocalization with eye-contact) were typical for the child, but far less common for the apes. This direct comparison of the development of members of three species of apes when raised in similar environments provided support for the gestural theory of language development but also suggested that increasing multimodal communication (or pairing of gestures and vocalization) supported the emergence of language among the ancestors of humans.

Conclusions

Although some of the evidence put forth in support of different adaptations of the gestural theory of language evolution has turned out to be less accurate than other evidence over time, a substantial body of evidence from multiple domains of research has been put forth to support gestural theories of language evolution. This body of evidence has grown increasingly more robust over time. Therefore, available evidence strongly suggests that gestures played an important role in the evolution of language and supports a version of the gestural theory of language.

However, evidence that gestures preceded rather than co-occurred with vocalizations in supporting the evolution of language remains very limited. Given that many researchers believe that language is currently multimodal (e.g., Arbib et al. 2008; McNeill 1985), gestural theories of language evolution may be more parsimonious if adapted into a multimodal theory of language evolution, wherein human language evolved from, and continues to utilize, mutually informative gestures and vocalizations (Armstrong 2002; Masataka 2008). Indeed, Hewes cited Condillac as one of the earlier scholars to put forth a gestural theory of language. However, Condillac and Aarsleff's (2001/1746) description of the process by which language evolved is more consistent with a multimodal than a gestural theory of the evolution of language. Condillac stated that spoken language developed from a "language of action" which consisted of a combination of gestures and vocalizations wherein our ancestors connected their "cries with some movement, gesture or action that made the expression more striking." (Condillac and Aarsleff 2001/1746, p. 114).

Girls Psychological Bullying

Definition

Bullying is a strategic, goal-oriented, and malicious behavior that harms individuals who have less power (Volk et al. 2014).

Introduction

Although girls' psychological bullying is a broad term that could apply to one's reaction of being physically assaulted, we define it as a behavior centered on spreading rumors, manipulating, criticizing, socially excluding, or assassinating the character of victims (SooHoo 2009). Indirect targeting behaviors that stem from relational bullying (e.g., rumor spreading) often occur with, but prior to, direct bullying behavior (e.g., rejecting the victim in front of a group) (Besag 2006; Letendre and Smith 2011). Regardless of the mode of aggression employed by bullies, the harm caused to victims of psychological bullying can be significant (Besag 2006). Whether girls are receiving benefits from using psychological bullying, as well as what their motivations may be, will be considered.

Evolutionary Motives Behind Girls' Psychological Bullying

Bullying appears to offer the same benefits to girls as it does for boys, namely increasing resources,

reproduction, and reputation/dominance (Volk et al. 2014). Specific to girl versus girl bullying, the potential motives behind this often psychological bullying may be related to the evolutionary concept of intrasexual competition and the desire to protect one's kin. Psychological bullying protects bullies' self-esteem and increases their marketability (Besag 2006). In an effort to appear as an eligible candidate to prospective mates, girls may use verbal and relational aggression to psychologically and socially devalue their competitors' worth and/or promote their own value as potential mates (Volk et al. 2012). The increased probability of achieving adaptive goals is a compelling incentive that negatively reinforces bullying behavior (Volk et al. 2012). Attractiveness conveys the message that a female is fertile and has high genetic quality, which is critical for reproductive investment (Hrdy 1979). Researchers have found that according to their peers, girls who bully are not only viewed as more attractive and popular but they also have greater access to reproductive opportunities and dating partners (Volk et al. 2014, 2015). On the other hand, girls who are more attractive and/or who date frequently are often targeted as victims by other girls, presumably as a form of intrasexual competition (Volk et al. 2012). This intrasexual female victimization has been linked to the development of eating disorders as well as to internalizing problems such as depression, anxiety, and suicidal ideation (Duarte et al. 2015). Thus, it appears to be an effective, if antisocial, solution to dealing with potential competitors.

Females' quest for reproductive status cannot be separated from their ambition to keep themselves and their offspring alive (Hrdy 1999). Women's reproductive output/success is likely to be equally, if not more so, influenced by parental care as it is by mating opportunities (Hrdy 1999). Achieving a dominant position within the context of a power imbalance allows girls to psychologically bully or exploit others who have visible signs of weakness (e.g., not having many friends) (Besag 2006). This may allow improved access to resources for the bully and their offspring as the victim is unable to mount an effective counter-response to the bully's psychological aggression

(Volk et al. 2012). Emanating social dominance is also valuable for preventing victimization and future threats to kin (Letendre and Smith 2011). For instance, great apes that are heavier than non-pregnant rival females can protect their newborn kin from infanticide, whereas the infants of subordinate great apes are considerably at risk of being killed by rival females (Hrdy 1979). Also, dominant rhesus macaques and squirrel monkeys can prevent subordinate mothers from retrieving their own infants (Hrdy 1999). It is likely that amongst humans, dominant women's children are less likely to be harmed or hindered.

However, there are limits to female bullying. Mothers are the most important feature of an infant's environment with regards to increasing an infant's chances of survival, followed by maternal grandmothers and elder sisters (Sear and Mace 2008). A substantial study examining the effects of kin on children's survival found that loss of a father did not affect the mortality of children, whereas loss of a mother increased children's odds of death by 99 % (Sear and Mace 2008). As the higher investing parent, it is crucial for mothers to maintain a high level of maternal care that is not adversely affect but too much overt aggression. Girls therefore avoid physical injury by adopting less risky psychological, as opposed to physical, forms of aggression that are nevertheless potentially effective at securing status, protection, and the ability to produce high quality offspring (Besag 2006; Hrdy 1999). For these reasons, boys are much more likely than girls to engage in physical aggression, while the sexes are roughly equal in their usage of verbal and social psychological aggression (Volk et al. 2014).

Conclusion

Psychological bullies use aggression within the context of intrasexual competition to achieve psychological benefits to themselves while at the same time imposing psychological harm/costs on their competitors (Besag 2006; Volk et al. 2014). For teachers, parents, and authority figures, efforts to address psychological bullying can be especially time consuming and laborious in comparison to overt physical bullying (Besag 2006).

Societal expectations depict bullying as normal and offer poor suggestions for how girls should overcome victimization (e.g., talking it out with the bullies, generating compassion) that do not coincide with evolutionary theory (SooHoo 2009).

Since bullying is considered an adaptive behavior, researchers suggest encouraging bullies to replace their behavior with socially just and effective alternatives, rather than trying to stop their harmful behavior or elicit empathy for victims (SooHoo 2009; Volk et al. 2012). Other effective methods for decreasing girls' bullying include increasing the rewards for compliance, the presence of visible and supportive peer mentors, and providing girls with the opportunity to learn valuable life strategies such as listening, compromising, and dealing with conflict (Letendre and Smith 2011). In order to successfully intervene, we must be more sensitive to the costs and benefits associated with girls' psychological bullying.

Girls' Interest in Familial Care

Lindsay A. Coome
University of Toronto, Toronto, ON, Canada

Introduction to Girls' Interest in Familial Care

Girls demonstrate a greater interest in familial care than boys, and this bias emerges early in development. Girls seek out childcare opportunities more often than boys and are more responsive to infants (Maestripieri and Pelka 2002). Compared to males and multiparous females, young nulliparous women show greater visual attention toward infant faces (Cardenas et al. 2013; Maestripieri and Pelka 2002), as do nulliparous female rhesus monkeys (Waite et al. 2007). It has been suggested that this attentional bias toward infant faces may reflect a developmental mechanism directed at preparing nulliparous females for motherhood by increasing the likelihood that they will gain the experience and parenting skills needed to raise their own offspring. Waning attraction to infants in older multiparous females is consistent with idea that the function of juvenile interest in infants is to facilitate the acquisition of parenting skills.

Play Parenting

Girls' interest in familial care is especially reflected in play parenting, which girls engage in more often than boys. The sex difference in play

parenting emerges in preschool and becomes more pronounced throughout development (Byrd-Craven and Geary 2007). Play parenting generally takes the form of handling or playing with an infant or infant substitute (e.g., dolls) and has been documented in both Western and traditional societies. It has been proposed that play parenting evolved to provide practice and experiences that improve later parenting skills (Pryce 1993; Byrd-Craven and Geary 2007).

In support of this idea, early play parenting experiences significantly improve the survival rate of firstborn offspring in many primate species (Pryce 1993). While primate studies suggest that juvenile play parenting experience is not necessary for the expression of maternal behavior, it does serve to improve parenting skills to some degree (Pellis and Pellis 2006). Females reared in socially impoverished environments with few opportunities to interact with infants show deficiencies in maternal behavior (Maestripieri and Roney 2006). Early experience with play parenting appears to improve mothering skills primarily by reducing the fear elicited by an unfamiliar infant. Adult female rhesus monkeys without play parenting experience spend less time in close proximity to their infant and exhibit more fear-related behavior toward the infant (Pellis and Pellis 2006). Human and animal studies have indicated that the amygdala plays a role in the development of appropriate responsiveness to infants, and young female rhesus monkeys with lesions of the amygdala fail to exhibit the species-typical interest in infants and infant handling (Toscano et al. 2009), suggesting that the amygdala may provide the neural basis for juvenile play parenting behavior.

Biological Basis of Play Parenting in Humans

While it has been argued that human sex differences in play parenting are due to differential socialization pressures, several studies have shown that sex differences in play parenting are related to prenatal androgen exposure. Girls affected by CAH show reduced interest in infant care (e.g., babysitting), and play with dolls less

frequently (Byrd-Craven and Geary 2007). Fetal testosterone in normally developing children has also been linked to sex-typical play behavior (Auyeung et al. 2009), as has testosterone measured in infancy (Lamminmäki et al. 2012). Evidence from twin studies suggests that genetics may play a role in sex-typed play behavior, including parental play (Byrd-Craven and Geary 2007). These studies suggest that sex differences in children's interest in play parenting cannot be explained entirely by the effects of gender socialization.

Conclusion

Sex differences in parental play and juvenile interest in infant care reflect sex differences in parental investment and plausibly evolved to allow for the practice of the skills and/or competencies needed for later reproductive success. Women have a greater interest in babies and engage in more play parenting as children. Studies attempting to demonstrate the role of parental and societal influences on the development of this sex difference have largely failed to do so (Maestripieri and Roney 2006), and evidence suggests that genetic factors and prenatal exposure to gonadal hormones play a role in the development of sex-typical interest in infants. Early female interest in familial care and engagement in parental play likely reflects a developmental adaptation that allows individuals to develop appropriate emotional responses toward infants, thereby improving parenting skills and increasing offspring survival.

The ability to make inferences about the causes of human behavior.

Introduction

A hallmark of human cognition is the capacity to read beneath the surface appearance of behaviors. Being able to see beyond the physical properties of an action and interpret it in terms of underlying intentions is integral to successful social functioning. Driving safely, negotiating job offers, playing a tennis match, and engaging in a conversation all require on-line, moment-to-moment predictions about other people's actions. When observing another person perform an action, adults and children typically fixate the goal of the action before it is completed (Flanagan and Johansson 2003).

Goal Detection is Precocious

Given that we live in a world of perceived intentional agents, an important question is, at what age are the actions of others perceived as guided by intentions? Over the past 20 years, researchers have developed sophisticated techniques (such as habituation) to address this question in preverbal infants. The findings from this research have shown that infants, like adults, can attribute goals to others (Robson and Kuhlmeier 2016). During the first year of life, infants appreciate the goal directedness of successful intentional actions. In one body of work, researchers showed that 6-month-old infants visually anticipate other people's actions that they were familiar with, and are later able to visually anticipate others' unfamiliar, more complex actions by 12 months of age (Gredebäck and Daum 2015). For example, infants who view feeding actions anticipate the arrival of the spoon at the mouth and, like adults, quickly disengage from the hand and fixate on the goal of the ongoing action (the mouth) just before the hand reaches this location. Although these findings suggest that infants can predict actions from early in life, it is unclear whether they anticipated the goal *per se* because the goal and motion path are confounded. In other words, after observing a spoon repeatedly moving to the mouth, a gaze shift to the goal is also a gaze shift to the endpoint of a familiar trajectory. A more conservative test would require that infants' predictions be tested when the context has changed, so that the same goal is reached with a different movement.

In an influential study, Woodward (1998) addressed this issue. In a procedure that has since become widely utilized, 6- and 9-month-old infants first watched as a hand moved out onto a table containing two objects. The hand would approach and grasp one object from the pair and would remain in this position until the end of the trial. This action was repeated upon the same object until the infants habituated (i.e., their looking time to the event decreased significantly). At this point, the locations of the objects were switched, and the hand reached either toward the same object in a new location or the previously

untouched object in the familiar location. Infants dishabituated (increased looking behavior) to the latter, indicating that they encoded the original reach as directed to a particular object. Interestingly, in a control condition where a claw replaced the human agent, the infants looked randomly, unless a person controlled the claw. The same procedure, with the switch of the target object location, showed that infants as young as 11 months made their first look from the hand to the goal object, now in a new location but looked first at the familiar location when a claw is the agent. Other studies have replicated these findings by changing the motion of the arm toward a single object. After infants were habituated to an actor reaching over a barrier with an arcing motion to retrieve a ball, the barrier was removed and infants saw the actor reach directly for the ball (i.e., same goal, a new path) or indirectly (i.e., old goal, same path). Infants looked longer at the indirect than at the direct test event, even when computer-generated agents were the actors (Phillips and Wellman 2005). Finally, it is worth mentioning that evidence of goal detection does not come exclusively from visual habituation experiments, but comes from overt social behaviors as well. For example, 7-month-olds will select the toy that an actor has grasped over another one that she simply touched with the back of her hand.

Can Infants Detect Failed Goals?

A critical test for understanding the depth of goal detection is one that requires reasoning about the goal of a *failed* action. The attribution of a goal when it is unfulfilled requires to reason more deeply than about the visual appearance of the action because the goal is opaque in the outcome or actor's action. The first demonstration of this ability came from a study by Meltzoff (1995) who showed 18-month-old infants an actor who tried, but failed, to perform several actions on objects. When given the opportunity to imitate the model, infants performed the action the experimenter intended to do (but never actually did) as often as those who had seen a demonstration in which the actor achieved his goal. This experiment has

been replicated and extended to younger infants and there appears to be a developmental progression in infants' ability to infer a goal from surface behavior between 12 and 18 months of age. There is also a developmental continuity between successful goal detection measured through a looking time measure at 10 months and failed goal detection measured through an active imitation task at 14 months (Olineck and Poulin-Dubois 2009).

The findings of recent studies suggest that infants' understanding of failed actions might even develop during the first year of life when a simple, familiar action (e.g., reaching) is tested with looking time procedures or in a toy sharing situation. By 9 months of age, infants show more patience when someone tries but fails to give them a toy than when she appears to intentionally prevent the infants from getting the object (i.e., teasing). When the test of goal detection with an arm successfully reaching over a barrier is modified to include a failed-action condition, infants as young as 10 months also look longer at the indirect than at the direct test event.

Is Goal-Detection Species-Specific?

What is the evolutionary origin of the precocious human ability to understand and predict the behavior of others? Do other animal species, especially our nearest relatives the chimpanzees, also understand the intentional actions of others? Recent studies have yielded results similar to those reported previously for human infants. For example, chimpanzees spontaneously (without training) behave differently depending on whether a human was unwilling or unable to give them food. They produce more behaviors and leave the testing station earlier with an unwilling compared to an unable (but willing) experimenter. Goal-based action predictions have recently been tested in great apes, including bonobos, chimpanzees, and orangutans, with the eye-tracking technology (Myowa-Yamakoshi et al. 2012). In the first attempt to adapt eye-tracking technology to chimpanzees, Myowa-Yamakoshi and colleagues reported that when chimpanzees observed actions such as pouring juice, they anticipated an action

goal in the same way as human adults. On the other hand, 8-month-old infants showed no evidence of goal anticipation. 12-month-old infants showed mixed evidence in that strong goal anticipation was not observed, but these infants did show weak predictive tendencies that were comparable to those of human adults and chimpanzees. Interestingly, infants scan goal-directed actions differently such that they spend more time looking at the face.

Another piece of important evidence comes from a study conducted by Kano and Call (2014). The researchers tested bonobos, chimpanzees, and orangutans that were familiarized to movie clips of a human hand reaching to grasp one of two objects. Then, as in the standard goal attribution task, the objects' locations were swapped, and in the test event, the hand made an incomplete reach between the objects. A mechanical claw performed the same actions in a control condition. The results were similar to those reported previously for human infants, and predictive looking did not differ among the three species of great apes. In a study including three preferential looking-time experiments on macaques, modeled on previous work on human infants (Rochat et al. 2008) tested whether macaque monkeys are sensitive to the functional efficacy of familiar goal-related hand motor acts performed by an experimenter. Like human infants, macaques gazed longer at less efficient actions (e.g., arching gesture in the absence of a barrier).

What about goal attribution in nonprimate species? To our knowledge, only one study has been conducted to address this issue. Adopting the same task as used in human infants, researchers presented dogs with either an inanimate agent (a black box) or an unfamiliar individual interacting repeatedly with one of two distinct objects (a globe vs. a watering-can). Once the dogs were habituated to the scene (habituation phase), the position of the objects was switched (test phase). The dogs were then exposed to three trials, in which they saw the agent (animate or inanimate) interact with the usual object (in the new location). This was followed by three subsequent trials in which the agent interacted with the

new object (in the familiar location). The dogs showed a similar response pattern relative to infants, in that they looked longer during the new goal than old goal trials. No such difference emerged with the inanimate agent (the black box) (Marshall-Pescini et al. 2014).

Conclusion

The rich literature on goal detection and attribution across species reviewed in this entry brings up the issue of the underlying mechanisms driving the perception of human actions as goal-directed. Is this type of behavior based on mentalistic processes or on simple learned associations? Some research has shown that performance on a goal-encoding task at 6 and 7 months of age is linked to implicit and explicit false belief reasoning years later. Such developmental continuity suggests that goal detection could be a precursor to later intention reasoning. A number of authors have suggested that an understanding of goal-directed actions, even in human infants, does not necessarily imply an understanding of mental states. Alternatively, other authors dismiss the looking time studies arguing that such data only provides evidence for infants' abilities to form statistical associations during the course of an experiment. Finally, the role of mirror neurons in goal detection has received much attention. Mirror neurons are visuomotor neurons that discharge both when a person performs an action and when that person observes someone performing a similar action (Rizzolatti and Craighero 2004). Whether mirror neurons are an innate evolutionary endowment or are gradually activated in response to learned actions is currently a topic of debate.

Goal attribution is a complex process and there is a wealth of information available to the viewer when watching someone who is performing a goal-directed action. In conclusion, the literature on goal detection suggests that human and non-human primates do not simply perceive the behaviors of others, they also interpret it. In human infants, researchers have documented a developmental trajectory in which the early intentional understanding of actions appears later than the

more precocious action- and object-based understanding. An important question in contemporary research on the developmental origins of goal detection is whether infants' understanding of intentionality is dependent on experience with human actions or more abstract, that is, detected in the actions of nonhuman entities.

The goal of sex education is to reduce sexually transmitted infections (STI's), HIV/AIDS, and unintended pregnancy among young people.

Introduction

The goal is to review research conducted on sex education in schools and to evaluate the goals of such programs from an evolutionary psychological perspective. This review aims to examine the effectiveness of sex education through a discussion of the environmental factors that influence adolescents' sexual life trajectories. Furthermore, the review discusses implications of these trajectories and works to determine how best to align each strategy with individual adolescent behaviors.

The primary goal of sex education is to reduce STI's, HIV/AIDS, and unintended pregnancies

among young people. Sex education, in school, is divided by various approaches to prevent negative health outcomes for adolescents. Sex education programs are typically either abstinence-only, or they are comprehensive approach. Abstinence-only approaches teach adolescents to avoid sex outside of marriage, and typically do not address birth control or safe sex methods. A comprehensive sex education approach focuses on a sequential program that focuses on multiple dimensions (e.g., physical and emotional) of sexuality and helps to inform decision-making. This approach equips adolescents with the necessary education on contraception use to reduce the spreading of HIV/AIDS, STI's, and unintended pregnancies. This review will examine the research done on the effectiveness of both approach type programs in light of adolescent's environment.

Life History Strategies and Risky Adolescent Behavior

Life history theory highlights that all people face a fundamental trade-off between investing into longevity and growth (i.e., building physical and mental capital through knowledge and skills) or reproductive efforts that involve sex and reproduction. Those that invest largely in reproductive effort at the expense of growth, maintenance, and longevity can be categorized as following a faster strategy, whereas those that invest heavily in longevity and growth and delay reproduction can be categorized as following a slower strategy (for a review, see Griskevicius et al. 2011).

Children who experience a significant amount of stress in their environment during childhood (e.g., insecure attachment, stressful family interactions, poverty) are prone to carry out strategies consistent with the fast life history trajectory in their adolescent years (for a review, see Kenrick et al. 1996). Rates of adolescent birth, pregnancy, and STD infection are higher among racial and ethnic minority groups, and these differences are often attributed to poverty, which is more common among these groups. Contraceptive use at first intercourse is also associated with poverty

status and race/ethnicity (for a review, see Santelli et al. 2000).

In a study examining life expectancy, neighborhoods with the highest life expectancy had mothers giving birth at a median age of 27.3 years, whereas in the neighborhoods with lowest life expectancy it was 22.6 years. The same pattern emerged in a study examining the relationship between violent crime rates and age of reproduction across 373 counties in the USA that represent over 146 million people. Higher violent crime rates were associated with earlier ages of reproduction, even when controlling for socioeconomic status (SES) (for a review, see Santelli et al. 2000).

Rational for Sex Education in Schools

In the USA there are 19.7 million new STI's diagnosed among adolescents each year. In addition, there is an estimated 614,400 pregnancies among girls aged 15–19, over 80% are unintended (for a review, see Finer and Philbin 2013). While there have been fewer pregnancies over the years, there is still great disparity in sexual health outcomes among adolescents living in low socioeconomic status communities (Centers for Disease Control and Prevention (CDC) 2013; Kost and Henshaw 2014). The high rates of STI's and unintended pregnancies in disadvantaged communities can be connected to behaviors and patterns among adolescents raised in high stress environments. While 95% of young people in the USA report some sort of formal sex education, in a school or community setting by the age of 18 (for a review, see Finer and Philbin 2013).

What Is Sex Education and What Are the Current Goals?

Sex education programs are typically an abstinence-only or comprehensive approach (also referred to as abstinence-plus). The abstinence-only approach focuses on teaching abstinence, from all sexual activity, as the only

acceptable behavior for unmarried adolescents (Visser and van Bilsen 1994). The comprehensive approach equips students with knowledge on the usage of contraceptives to reduce the risk of unintended pregnancies and sexually transmitted diseases. Research shows that such programs have helped decrease behavior that puts young people at risk of STI's, HIV, AIDS, and unintended pregnancies (for a review, see Finer and Philbin 2013). Rather, than influencing teens to engage in earlier sexual activity, comprehensive knowledge and access to contraception will equip older teens who already engage in sexual activity with the proper resources (Boonstra 2011).

Implications for Intervention

By better understanding how unhealthy sexual practices have evolved as an adaptive outcome for disadvantaged groups, sex education will be better able to guide adolescents in healthier and more desirable directions. Abstinence-only approach may have little impact on young people growing up in stressful environments and who see limited value in preparing for their future (for a review, see Frankenhuis and Del Giudice 2012). With this in mind, it would be more effective to teach adolescents to think about delaying immediate benefits like early childbearing, due to the potential costs (i.e., possible job and educational losses) (for a review, see Frankenhuis and Del Giudice 2012).

Conclusion

Intervention goals which address strategies that are aligned with adolescent's evolutionary motivated behavior will be most effective in the primary goal of promoting positive health outcomes among adolescents. If the goal of school-based sex education is to increase positive health outcomes for youth, comprehensive (or "abstinence-plus") sex education has far more research to support it as an effective method of sex education. Abstinence-only programs run the serious risk of

leaving young people, especially those who are at elevated risk, uninformed, and at-risk for poorer life outcomes (for a review, see Ellis et al. 2012).

Definition

A set of genes that carries the best adaptive characteristics and genetic traits that promote the selection of evolutionary tools, such as adaptability, health, or genetic variability.

Introduction

Sexual selection is a complex process and involves many variables still not completely clear to researchers. Among these variables, there is one called “good genes,” an indirect benefit that cannot be observed directly but has hypothetical indicators of masculinity, symmetry, health, and physical attractiveness.

The Role of Good Genes for Sexual Selection

Selecting the ideal partner involves the analysis of several factors. The best option for a long-term relationship not always seems to be the same for a short-term relationship. This is because, according to the sexual strategies adopted or the period of the sexual cycle (as in ovulation), the valued characteristics change, mainly for females (Penton-Voak and Perrett 2000).

As sexual evolution adjusts to evolutionary pressures, it is quite feasible to favor or prefer genetic benefits (good genes), even if implicitly. Research has shown that female, when looking for partners for short-term relationships, for reproduction, or when they are in the fertile period, usually values the so-called good genes more. Producing offspring with better genetic characteristics would be the most urgent goal, ensuring reproductive success and improved adaptive characteristics (Gangestad 2000; Roberts and Little 2008). However, assessing which individuals have good genes is not a direct task, since only the phenotype is accessible externally. This does not pose a problem, since subjects look for traits that may indicate the partners’ genetic qualities or complementary genes. Studies show that visual, olfactory, and auditory characteristics are used to select good genes, especially among females (Roberts and Little 2008).

These characteristics would be read as indicators of some adaptive advantages: a muscular body would indicate physical strength, an important characteristic of survival and protection, even more if associated with torsos with a form of “inverted triangle”; the shape of the body would indicate physical strength; height would indicate reproductive success; symmetry would indicate precision in development; and virility and skin health would indicate general health. In addition to these indicators, extreme traits of dimorphism, height, and muscles are usually avoided because the indicators could indicate developmental and/or environmental maladjustments. The exaggeration of these characteristics, which in the right measure would be good indicators, in excess would be unattractive (Buss and Shackelford 2008; Gangestad 2000; Roberts and Little 2008; Swami et al. 2007).

In addition, high levels of sex hormones would be related to a better immune system. For example, the immunocompetence handicap hypothesis suggests that testosterone-based male ornaments are honest signals of immune function, because testosterone suppresses immune function, so the ability to have high testosterone and yet still have a good immune system is an indicator of good genetic quality, while estrogen influences

the immune profile females adopt by suppressing cell-mediated immune function and enhancing humoral-mediated immune function (Foo et al. 2017). A better immune system is an indicator of good genetic quality. Besides that both estrogen and testosterone modulate facial features, such characteristics could be an indicator of good genes. An efficient immune system would be one of the best indications of good partner genetic material. This adds to findings on skin health and masculinity as indicators of good health (Sefcek et al. 2007; Thornhill and Gangestad 1996).

The theory of “good genes” is reinforced by some particularities found in studies of birds and mammals. Among the latter, males mostly do not offer parental care, and therefore it is the indicators of good genes that are decisive for the females’ sexual choice. In most species, such as in primates, a combination of underlying genetic characteristics and indicators of parental care and resource provision is likely to occur (Gangestad 2000). In turn, women appear to have evolved to mixed-breeding strategies (Buss and Shackelford 2008).

Extra-pair copulation, which seems to be a search for good genes, emerges in this context. Some bird species privilege paternal care for their choice of partner but have a high rate of extra-pair cases with individuals presenting indicators of good genes, such as symmetry. An increased number of extra-pair cases increases the genetic diversity of the population. Other evidence would be that these relations occur more in the fertile period, as well as the fact that males who are more symmetric have more partners and are more often chosen for this type of relation. Women in fertile periods prefer the smell of symmetrical men; another characteristic is the preference for more masculine faces for short-term relationships (Gangestad 2000).

Women’s physical attractiveness is taken as the main indication used by men to select good genes. On the other hand, women consider a greater number of variables (especially attraction-related ones, which have high market value), categorized into good genes, investment indicators, and indicators

of good parenting and good partnership: virility, physical attractiveness, sexual attractiveness, physical fitness and beauty, as well as other social benefits (Buss and Shackelford 2008).

Conclusion

Thus, the search for good genes seems to encourage competitiveness in the selection of sexual partners. As genetic traits are not easily observed, other traits and behaviors provide indicators of what would be good genes to be transmitted to the offspring, such as physical attractiveness, symmetry, and strength. In this process, gene variability acts on the development of strategies for partner retention and the adaptive skills and abilities necessary for the survival and perpetuation of genes.

Definition

Good health refers to a harmonious state of mind, body, and soul, in the absence of any illness, disability, or deformity.

The future that is consistent, steady, sustainable, productive, and promising is considered as stable future.

Introduction

Health is an important determinant of survival or sustainability of an individual. Since ancient times, the human focus mostly remained on maintaining a healthy state. The basic needs of life (food, shelter and sex) intend at restoration of health and survival. The theory of evolution of Charles Darwin emphasizes about survival of the fittest in the evolutionary race. The survivors are the fittest. To become fittest, an individual need to be healthy enough to overcome natural adversities. Since times immemorial, health gained importance as human beings tried to overcome sufferings (sorrow, trauma, pain, disability, poverty) by various means. There is always an intense human desire to remain in a healthy state; probably this need has given birth to the science known as *medicine*. An individual will have a future, only if he or she survives. Survival needs a healthy state of the individual in a healthy environment with adequate resources for survival. Thus, it is amply clear that there cannot be stable future without good health.

Evolving Concept of Health

Researchers and philosophers earlier attempted to define health, which are still acceptable in the modern medicine. Greek philosopher Plato emphasized the relevance of harmony between the individual and its environment for having good health as the Greeks believe good health as “*a healthy mind in a healthy body*” (Svalastog et al. 2017). Similarly, Pinder in fifth century defined health as a state of “harmonious functioning of organs” (Svalastog et al. 2017).

World Health Organization (WHO) defines health as “a state of complete physical, mental and social well-being and not merely the absence, of disease or infirmity” (World Health Organization 2014; Svalastog et al. 2017). This definition was adopted in 1948; however, over past 70 years, significant changes have occurred in the determinants of health and health care needs. Many researchers argue that the existing definition of health given by WHO fails to address

all the domains and determinants of health; hence, there is need to redefine health. It is proposed to incorporate “spirituality,” “adaptation,” and “equilibrium between human and nature” in the universal definition of health (Charlier et al. 2017; Nobile 2014). For e.g., peace cannot be defined as mere absence of war, it is much more than that. Similarly, instead of classical biomedical definition of health, we need to move to socioecological concept of health which is known as “New Public Health” (Fien 2010). This concept of New Public Health has evolved gradually over last 20 or so years. The fundamental conditions and resources for health under this concept have been enumerated in Table 1.

Good health refers to a positive state of health. For achieving good health, there should be a

balance between the internal environment and external environment of the individual. The internal environment of an individual consists of mind, body, and soul, which refers to the mental health, physical health, and spiritual health, respectively (Cumbie 2001). The external environment refers to family and community in a narrower sense to the national and global scene in a broader sense. The holistic view of health as conceptualized under “New Public Health” has laid strong emphasis on the fact that health of people, health of communities, and the health of natural environment are closely interlinked, at local, national, and global levels (Fig. 1).

Determinants of Good Health

The determinants of health are broadly of two types, viz., personal and environmental (Brown and Closser 2016). The personal determinants are the individual specific characteristics and the environmental determinants are specific environmental factors that significantly influence health. For having good health (a healthy state of mind, body, and soul), there should be optimal functioning of all the organs of the body along with sound and harmonious state of mind. These should be supplemented with fulfillment of spiritual needs, financial needs, sociocultural stability, and availability of adequate resources and support. An

Good Health and Stable Future, Fig. 1 Integration of good health with stable future

equilibrium needs to be maintained between the individual and its environment to make the individual adaptable to its environment.

Evidences suggest inequality of income stands as an obstacle of health and social cohesion, as a result of which health is adversely affected (Kawachi and Kennedy 1997). Nutritional inequality also adversely affects the health. Individuals from low socioeconomic status suffer more from nutritional deprivation and have compromised health (James et al. 1997). There are many other factors that directly or indirectly affect health in an adverse manner. These factors are – poor education leading to unawareness, racial discrimination, lack of legislations and policies related to health, funding for health, availability of health infrastructure, and political commitment (Braveman et al. 2011). Countries having strong health policy have better health infrastructure, adequate health care resources, and better health care delivery facilities at the primary care level in a reasonable cost, which has strong impact on the health of countryman (Starfield and Shi 2002).

Determinants of Stable Future

Probably, the best way to conceptualize stable future is to understand the sustainable development goals (SDGs) laid down by United Nations Development Programme (Table 2) (Fien 2010).

While framing these goals, it has been tried to inculcate all the possible factors that shall lead to achieve a state that is steady, stable, consistent, sustainable, productive, and promising. It is noteworthy that stable and sustainable future incorporates development and security of individual, community, and environment separately as well as collectively. It is also possible to summarize the essence of 17 SDGs into four dimensions viz. social, economic, ecological, and political. Achievement of stable future depends on simultaneous and balanced progress in all these four dimensions which are again totally interdependent (Fig. 1).

Integrating Health with Future

From the above discussion, it is amply clear that health and future are closely interlinked and there is no way one could be separated from the other.

Good Health and Stable Future, Table 2 United Nations’ sustainable development goals

No poverty
Zero hunger
Good health and well-being

Affordable and clean energy
Decent work and economic growth
Industry, innovation and infrastructure
Reduced inequality
Sustainable cities and communities
Responsible consumption and production
Climate action
Life below water
Life on land
Peace and justice strong institutions
Partnerships to achieve the goal

Among the 17 SDGs listed in Table 2, three are directly related to health and the rest are actually working towards achieving these. There can neither be good health nor stable future if people are experiencing social, economical, or political instability, or if the environment is ignored in race of development.

If health is analyzed across the lifespan of an individual, successful completion of the life stages is important for meeting the future needs. Evidences suggest that early life adversities (e.g., abuse and neglect during childhood) are likely to affect the future of the individual. Health care needs of different stages of life are different. Hence, understanding the health care needs of different stages of life continuously and meeting them adequately will help in maintaining good health and may give a stable future.

Conclusion

As good health is a major determinant of stable future, health promotion is likely to brighten the stable future. Attainment of good health is possible not merely focusing on the physical health, rather equally focusing on all the dimensions of

health and maintaining a harmony between them. An individual with stable future is often considered to be having good health and individuals with good health shall have stable future.

Good Parenting Qualities

Parental behavior that facilitates child development

Introduction

Good parenting qualities are commonly defined as parental behavior that increases a child's chances of good health, happiness, and success. Such parental behaviors can include everything from the provision of fundamental resources, such as nutrition and shelter, to modeling good relationship skills and encouraging a healthy lifestyle. Depending on cultural context and values, parental behaviors can also include different forms of education, spiritual guidance, and informing children about expectations and norms that will help them navigate society later in life. Understandably, what is seen as being good parenting is often determined by the effects parental behavior have on the child's personal development – the evaluation of which is, at least partly, defined by cultural norms and subject to variation over time.

Evolutionarily, parental behavior has been selected so as to optimize the parent's total reproductive output by balancing investment across both current and future children. Contrariwise, children's behavior has been selected to demand more investment from their parents than their parents are prepared to give (Trivers 1972). This means that although natural selection has promoted behaviors that increase the genetic fitness of parents and children, natural selection has not

necessarily promoted parental behavior that is commonly considered “good.” Neither has natural selection promoted unlimited investment in each individual child, as this would come at a cost to the parent’s total reproductive output. Thus, there may be situations in which there is a conflict between what is considered good parenting and the psychological adaptations of parents.

Parenting Behavior and Genetic Confounding

A litany of studies has aimed to investigate parental behaviors that have desired or undesired effects on children’s development. For example, meta-analytical reviews suggest that positive involvement, parental support, and positive affect are associated with desired child outcomes such as decreased relational aggression and higher academic achievement (e.g., Fan and Chen 2001; Kawabata et al. 2011). On the contrary, controlling behavior, negative affect, abuse, and parental neglect are associated with undesired child outcomes such as higher relational aggression, increased risk of delinquency, anxiety, and depression (e.g., Kawabata et al. 2011; McLeod et al. 2007). The strength of the observed associations is, however, usually only weak to moderate. In most cases, interpreting the findings of such studies as parental behavior having causal effects on child outcomes is complicated by the fact that a possible genetic confound has not been controlled for. In fact, a central precept of Darwinism is the genetic inheritance of traits from parents to children. This means that any gene that promotes behavior X (e.g., aggression) in the parent might be inherited to the child and promote behavior X (or even behavior Y [e.g., delinquency], if behaviors X and Y share genetic background) also in the child. For example, the observation that children with socially distant mothers display poor attachment, and that this predicts social dysfunctions in adulthood could be the result of genetic material being shared between the mother and the child. That is, a potentially correct observation of an association between a parental behavior and child outcomes might incorrectly

be considered causal, as sufficient evidence for actual causality is lacking (Barbaro et al. 2017). This lack of proper evidence for causal effects of parental behavior on child outcomes, and the fact that most associations between these two are weak, has been thoroughly discussed by Harris (2009), who additionally points out that many of the behaviors that parents attempt to influence in their children are also shaped by their peer groups. Interestingly, this suggests that parents might be able to influence child outcomes by trying to influence the social environment of their children.

Mothers and Significant Others

The extent of maternal investment that is necessary to produce and raise a child clearly outweighs the necessary investment of fathers. In comparison to most mammals, actual paternal investment in humans is nevertheless relatively extensive. The amount of paternal investment varies considerably between different cultures, and, because fathers are quite capricious caregivers, and human children demand large amounts of investment, it has been suggested that children historically depended greatly on investment from other maternal relatives and female kin (Hrdy 2009).

The selective forces behind the evolution of costly investment in children are contingent on the probability of shared genetic material. Inclusive-fitness theory (Hamilton 1964) postulates that the ratio between costs to self and benefits to other of a particular investment, weighted by the degree of relatedness (i.e., the probability of sharing gene copies due to common descent), dictates the selection pressure behind investing in close kin. Because there is a 0.5 probability that a copy of a particular gene in a parent is present in their own biological child and only a 0.25 (or smaller) probability for nieces or nephews, costly investment is expected to be larger in own compared to other’s children. Indeed, studies generally support this hypothesis. Both women and men invest more in own children compared to their nieces and nephews (e.g., Antfolk et al. 2017), and behaviors that negatively

affect a child (e.g., sexual abuse) are less likely to be directed towards own children compared to nieces and nephews (e.g., Kresanov et al. 2018). Although the lack of biological relatedness is reflected in relatively decreased positive investment and increased risk of abuse, investment in stepchildren, adoptive children, and foster children – who in the majority of cases are not biologically related to their caregiver – is in most cases considerably higher than investment in unrelated children outside the family (e.g., Antfolk et al. 2017). In this context, it is important to note that regardless of whether a child is the biological descendant of the parent or not, a particular parental behavior is likely to have similar effects on the well-being of the child in question.

Conclusion

A variety of parenting qualities has been associated with positive child outcomes. These include, for example, positive involvement, support, positive affect, and acceptance. However, associations tend to be weak to moderate, and proper evidence of a causal effect of parenting behaviors and child well-being has rarely been established. Although biological parents tend to display a greater willingness to invest in their children, many non-biological parents invest equally much, and the possible effects of parental behaviors are unlikely to depend on the degree of biological relatedness per se.

Gordon Orians

Kevin Bennett

Department of Psychology, Pennsylvania State University, Beaver, Monaca, PA, USA

Introduction

Gordon Howard Orians (born July 10, 1932) is Professor Emeritus at the University of Washington and a noted ornithologist and ecologist. He completed his PhD in Zoology in 1960 at the University of California at Berkeley and has been at the University of Washington ever since. His doctoral dissertation on social systems of marsh-nesting blackbirds was instrumental in establishing the emerging discipline of behavioral ecology. An investigator in the fields of ecology, evolutionary biology, and animal behavior, he is the author of numerous scientific journal articles and books and the recipient of many national and international awards.

American Blackbirds

As a vertebrate zoologist at the University of Washington, he focused his attention on American blackbirds of the family Icteridae due to his interest in the various types of avian social organization – territorial, colonial, polygamous, and brood parasitism. His work in this area produced theoretical papers as well as tests using experimental manipulations and comparative analyses of interspecific patterns. Many students will recognize Orians as the coauthor of a widely used introductory biology text (Purves et al. 1992). His scientific books include monographs on blackbirds and an edited volume on biodiversity in tropical forests.

Community Ecology

It is well-known but still surprising that in most environments herbivores consume a relatively

small proportion of the biomass of green plants. Orians pointed to the possible role of chemical defenses of plants against grazing as an explanation for this intriguing pattern in community ecology. He conducted research on the types of defensive chemicals synthesized by different kinds of plants, how their production may be stimulated by herbivore attacks, and how herbivores neutralize toxic chemicals produced by plants. Plant-defensive chemistry, he concluded, is part of the explanation for why the world is so green.

Savanna Hypothesis

According to the savanna hypothesis, our current habitat preferences were shaped by selection pressures in our ancestral past (Orians 1980, 1986). In a broad sense, the savanna hypothesis addresses the issue of how we select places to live and why we find some landscapes more beautiful than others. The theory argues that selection favored preferences, motivations, and decision rules that attract us to resource rich environments while avoiding environments populated with survival threats and lacking resources. The African savanna, widely believed to be the site in which humans originated, fulfills these requirements.

The details of the savanna hypothesis include three stages of habitat selection: *selection*, *information gathering*, and *exploitation* (Orians and Heerwagen 1992). The primary decision faced in stage 1 is whether to canvass or flee a landscape upon initial encounter. Assuming the experience in first stage is decent, individuals begin exploring the environment for resources and possible hazards. Stage 2, *information gathering*, involves mentally mapping the area for hidden places to harbor oneself, family, and allies. The decision of whether to stay or leave is at the heart of stage 3, *exploitation*. This final stage involves elaborate mental calculations that help to determine if one should stay long enough to enjoy the full bounty of resources available in the habitat.

Snakes, Sunrises, and Shakespeare: How Evolution Shapes Our Loves and Fears

In his book, *Snakes, Sunrises, and Shakespeare: How Evolution Shapes Our Loves and Fears*, Gordon Orians explores the role of evolution in human responses to the environment, arguing that many of our aesthetic preferences – from landscape beauty to food and entertainment – are the lingering result of natural selection.

Orians reveals how our lives today are shaped by decisions our ancestors made generations ago on African savannas. During this time humans selected places to live, sought food and safety, and socialized in small hunter-gatherer groups. Through this process specific likes and dislikes became wired in our brains, as the appropriate responses to the environment meant the difference between survival and death. He explains in rich detail why we prefer parks and gardens with tropical savanna elements, why we have developed discerning palates for wine, and why we find some odors unbearable.

Awards and Service to the Profession

In addition to his research in behavioral ecology, he devoted great effort to the interface between science and public policy. From the beginning of his career, Orians has taken an active interest in environmental problems, often taking positions within organizations that aid in the preservation of biodiversity. He was the director of the University of Washington's Institute for Environmental Studies for 11 years, served two terms on the board of directors of the World Wildlife Fund-US, and was the president of the Organization for Tropical Studies for 8 years. Orians has served his profession as a member of the US National Academy of Sciences and the American Academy of Arts and Sciences and is the past chairman of the Board on Environmental Studies and Toxicology of the National Research Council. In 1999, the Cooper Ornithological Society presented him with the Loye and Alden Miller Research Award for lifetime achievement in ornithological research.

Conclusions

For more than five decades, Gordon Orians has been an influential figure in the field of biology – especially on the topics of territoriality, habitat selection, mating systems, and population studies. Modern behavioral ecology owes a debt to his pioneering research.

Gossip and Grooming Hypothesis

Posits that language evolved as a means of forming and maintaining alliances when group size became too large for relationships to be managed solely through grooming

Introduction

The gossip and grooming hypothesis is an attempt to explain the steady and pronounced increase in hominid brain size over the last four million years. Developed by Robin Dunbar (1996), it begins from the premise that brain expansion was driven by the computational demands of monitoring, predicting, and manipulating the behavior of conspecifics. It sees language as one of the adaptations that evolved in response to these tasks. Specifically, it posits that language evolved as a means of forming and maintaining alliances when group size became too large for relationships to be managed solely through grooming.

Our primate ancestors lived in the tropical forests of Africa, but when these forests began to shrink around ten million years ago due to climate change, competition for food intensified. In response, some individuals began venturing onto the expanding savannas to make their living. This exposed them to greater predation risk, because open grasslands provide few avenues of escape. One way organisms cope with predation risk is by living in larger groups: the larger the group, the

more eyes and ears there are to detect predators and the lower the odds of becoming one of their victims. However, living in larger groups exacerbates competition over food, mates, and safe sleeping sites. Under these circumstances, stronger individuals can advance their interests by bullying weaker ones. In response to this problem, many primates have evolved the ability to form alliances with other group members in order to provide mutual support against harassment. In nonhuman primates and – presumably – early hominids, these alliances are formed and maintained by grooming. Geleda baboons are a case in point: There is a positive correlation between the frequency with which females are groomed and the frequency with which they are supported in agonistic interactions. Tellingly, primate species that form cooperative alliances – such as chimpanzees, baboons, macaques, and vervet monkeys – tend to live in comparatively large groups.

Although grooming is an effective bonding tactic, it is also very time-consuming. Thus, once group size expands beyond a critical threshold, grooming loses its effectiveness: As group size increases, individuals have to maintain increasingly larger grooming circles; this leaves less and less time for foraging until, eventually, groomers face starvation. Language solves this problem by enabling individuals to groom their alliance partners verbally: Instead of removing parasites, verbal groomers provide their partners with valuable information. Whereas physical grooming limits individuals to interacting with one partner at a time, language enables individuals to service several partners at once. Thus, by circumventing the time constraints of physical grooming, information sharing enables individuals to maintain a larger number of alliances. Dunbar argues that language evolution was driven not only by the need to manage alliances more efficiently but by the benefits of sharing information that is instrumental to alliance formation and maintenance – information about the interests, goals, relationships, and character of the occupants of one's social universe, including oneself. Others argue that language evolution was driven, at least in part, by the benefits of transmitting

ecological knowledge. This debate is part of a larger question about the selective forces that drove hominid brain expansion. Key to resolving this question is an understanding of the ecological niche to which humans are adapted and its implications for human cognitive design.

Hominid Brain Expansion and Colonization of the Foraging Niche

The gossip and grooming hypothesis is an offshoot of the social brain hypothesis, which is one of two main branches of thought regarding hominid brain expansion. The chief bone of contention between them is whether this process was driven by the demands of ecological or social information processing (Byrne and Whiten 1988). The ecological hypothesis posits that hominid brain expansion was driven by the demands of complex resource extraction and associated tasks such as wayfinding. In contrast, the social brain hypothesis posits that brain expansion in humans was driven by the computational demands of cooperation and social competition. The hypothesis originated in the 1960s and 1970s with Alison Jolly, Ralph Holloway, and Nicholas Humphrey but remained untested until the early 1990s (Dunbar 1996). A third framework (Tooby and DeVore 1987; Kaplan et al. 2000) synthesizes the ecological and social models.

Hominid brain expansion is a biological puzzle. The human brain has more than tripled in size since the emergence of the Australopithecines roughly 4 ma, from approximately 400–500 cc to 1400 cc (Dunbar 1996). Most of this expansion took place after the emergence of our genus, *Homo*, 2.8 ma. Large brains are unlikely to evolve due to the high metabolic costs of growing and maintaining them: Although the human brain comprises only 2 % of adult body weight, it consumes 20 % of total energy intake (Dunbar 1996). Thus, the high energetic costs of a large brain must be offset by commensurate benefits. This presents two questions: How can the high costs of a large brain be supported, and what are the benefits of investing in brain expansion?

An answer to the first question was proposed in the expensive tissue hypothesis (Aiello and Wheeler 1995), which argues that, since the liver and gastrointestinal tract are as metabolically expensive as brain tissue, the costs of encephalization can be offset by a reduction in gut size. This, in turn, can be achieved through diet. Digestion of large quantities of low-quality foods requires a large gut, while digestion of small quantities of nutrient-dense foods can be accomplished by a much smaller gastrointestinal system. Aiello and Wheeler (1995) found a pronounced negative correlation between relative brain and gut mass in primates: Species with relatively large brains have relatively small guts. The relationship between diet quality and brain expansion is supported by evidence that, in primates, large brains and neocortices are associated with omnivorous feeding strategies, which require complex extraction strategies (Byrne and Whiten 1988; Dunbar 1996). Further support comes from the finding that frugivores have larger brains than foliovores and that the former have larger home ranges, which may require more computational power due to the greater demands that frugivory makes on spatial reasoning (Dunbar 1996).

Much research on human brain expansion has thus focused on diet. Several lines of evidence indicate that the Australopithecine-*Homo* transition was characterized by increased consumption of energy- and nutrient-dense foods such as meat, nuts, and tubers. Tooth enamel analysis indicates that at least some Australopithecine species were omnivorous and that early *Homo* moved in the direction of increased dependence on animal foods (Balter et al. 2012). This finding is consistent with the pronounced reduction in posterior dentition and mandibular robusticity seen in early *Homo* (Leonard et al. 2007). Brain expansion almost certainly would have required an increase in the proportion of meat in the diet. This is because in mammals docosahexaenoic acid (DHA) and arachidonic acid (AA) are essential to brain growth (Leonard et al. 2007) and, on the African savanna, only wild ruminants provide moderate to high amounts of these nutrients (Leonard et al. 2007). Other good sources of DHA and AA are freshwater fish and shellfish,

but there is little evidence of their regular exploitation until much later in human evolution (Leonard et al. 2007). Cooking is another means of increasing dietary quality, but there is scant evidence for the control of fire before 1.5 ma (Leonard et al. 2007). A modest proportion (10–20 %) of meat in the diet would have been sufficient to support initial brain expansion (Leonard et al. 2007); however, modern forager diets indicate that a higher proportion of 45–65 % was needed to support expansion to *H. sapiens* levels (Cordain et al. 2000).

The social brain hypothesis argues that the dietary shift removed an energetic constraint on brain expansion, but was not a causal factor (Dunbar 1996; Leonard et al. 2007). While conceding that ecological selection pressures may have contributed somewhat to this process, Dunbar (1996) argues that the cognitive demands of the human feeding niche are not significantly greater than those of other primates. In a test of three versions of the ecological hypothesis, he found that neither the percentage of fruit in the diet, size of home range/length of day journey, nor degree of extractiveness in the diet predicted neocortex size in nonhuman primates. In contrast, neocortex size was positively correlated with social complexity, operationalized as group size. Using human neocortex volume to extrapolate a value for human group size from the primate equation, Dunbar predicted an average group size of 150, operationalized as a set of people who know everyone in the group as individuals. A survey of traditional forager and small-scale horticultural societies found that group size reliably hovers around 150. The same pattern is evident in the earliest farming villages in the fertile crescent, in twentieth-century Hutterite farm communities, and in modern horticulturalist villages in southeast Asia and South America (Dunbar 1996). In Western industrialized societies, many cooperative networks and units, such as church congregations and military companies, average around 150 members (Dunbar 1996). Further evidence that hominid brain expansion was driven by the demands of monitoring and managing the social environment comes from research on ability to track multiple-order intentionality. Tests

show that, beyond 4th-order intentionality, error rates increase significantly (Dunbar 1996), suggesting that processing multiple-order intentionality is computationally taxing.

The social brain hypothesis has been criticized on the grounds that it underestimates the cognitive software demanded by human foraging methods, a claim supported by research indicating that human extractive efficiency is nearly double that of nonhuman primates (Gaulin and Konner 1977). On this point, treating degree of diet extractiveness and social complexity as discrete phenomena obscures a key feature of the human ecological niche: the extraction of resources using complex techniques *and* cooperation. Use of these strategies enables humans to bypass their anatomical limitations and acquire resources that would otherwise be prohibitively costly or dangerous to access (Tooby and DeVore 1987; Kaplan et al. 2000). The use of these techniques is scaffolded by an extensive range of skill and knowledge sets: Human foragers depend so heavily on the acquisition, generation, transmission, and application of information that the foraging niche has been characterized as a “subsistence economics of information and knowledge use” (Barrett et al. 2007, p. 242). The quantity of information demanded by complex extraction exceeds an individual’s ability to acquire it by the onset of sexual maturity through first-hand experience alone (Boyd et al. 2011). The solution that evolved in response to this problem is social learning: Studies of cultural transmission in forager groups indicate that the bulk of subsistence-related skill and knowledge sets are acquired from conspecifics (Hewlett and Cavalli-Sforza 1986). Social learning greatly reduces the time and energy costs as well as the dangers of acquiring information through feedback learning.

Research in developmental and cognitive psychology indicates that a considerable proportion of human cognitive architecture is dedicated to the task of information extraction and transmission (Barrett et al. 2007). For example, the ability to reason counterfactually enables humans to generate new knowledge through experimentation and invention (Barrett et al. 2007). This capacity

enables the generation of mental models (Tooby and DeVore 1987), including representations of past, future, and possible scenarios (see entry on Narrative). These models reduce extractive risk and increase extractive efficiency by making it possible to simulate possible problems and test the effectiveness of alternative responses (Tooby and DeVore 1987). The ability to reason counterfactually emerges at around 15 months (see entry on Narrative), which is what we would expect if occupation of the foraging niche were dependent on the production and deployment of complex extraction techniques. Similarly, the ability to share attention emerges near the end of the first year of life (Baron-Cohen 2005), which is what we would expect if the foraging niche required a long learning period supported by information transmission. Social learning also requires shared intentionality or the ability to attain a goal by inferring the goal and copying the relevant actions of a conspecific (Tomasello et al. 2005). This in turn depends on the ability to make inferences about the mental states of conspecifics, or theory of mind. Theory of mind is integral to the acquisition of language, which greatly increases the efficiency of information transmission (Barrett et al. 2007), thereby facilitating teaching or *ostensive communication* – the demonstration of knowledge by experts and the recognition of this behavior by novices (Csibra and Gergely 2009). More broadly, theory of mind enables the strategic deployment of information to manipulate the beliefs, affective states, and behavior of conspecifics (Humphrey 1976; Byrne and Whiten 1988), which is useful for the transmission of precautionary information to children (Scalise Sugiyama 2011) but can also be used for darker purposes, such as tactical deception. And finally, social learning is subserved by an elaborate suite of mechanisms dedicated to social exchange (Cosmides and Tooby 2005). Although they most likely evolved in the context of food transfers, these mechanisms enable the exchange of resources of all types, including information. Additionally, the ability to cooperate in groups exponentially increases the productive capacity of human labor (Barrett et al. 2007), thereby

enabling social groups to accumulate and maintain vast stores of knowledge (Scalise Sugiyama 2011).

The interdependence of complex extraction and cooperation is illustrated by a fundamental problem posed by tool manufacture: The processes involved in making and/or utilizing complex extraction techniques cannot be inferred from the technology itself. This has led some researchers to hypothesize that language evolution was driven, at least in part, by the benefits of increased accuracy and efficiency in the transmission of tool technology (Csibra and Gergely 2009, p. 148). Experimental evidence supports this claim. Morgan et al. (2015) measured rates of transmission for Oldowan tool manufacture using five different learning techniques: reverse engineering, imitation/emulation, basic teaching, gestural teaching, and verbal teaching. The volume and quality of tools produced, and the rate at which they were generated, were highest in the verbal instruction condition. Conversely, little learning occurred in the reverse-engineering and imitation conditions. This finding attests to both, the complexity of human extractive methods and their pronounced dependence on cooperation.

The composition of the human forager diet points to the extractive challenges ancestral humans faced. Compared to other primates, humans are much more dependent on resources that require extensive knowledge to acquire. Kaplan et al. (2000) compared the chimpanzee and human forager diet on the basis of types of foods exploited: collected resources (foods that can be obtained and eaten simply by gathering them from the environment), extracted resources (nonmobile resources that must be separated from a protective context), and hunted resources (mobile resources that must be extracted and processed before consumption). While collected foods make up 95 % of the chimpanzee diet, they only account for 8 % of the forager diet. In contrast, the forager diet consists of 32 % extracted and 60 % hunted foods. Thus, 92 % of the human forager diet consists of extracted and hunted resources, compared to 5 % for chimpanzees. Additionally, compared to other animals,

humans exploit a greater diversity of prey species. A study of game taken between 1980–1996 found that Ache foragers utilized at least 78 different mammal species, 21 different species of reptiles and amphibians, probably more than 150 species of birds (more than the researchers were able to identify), and over 14 species of fish (Kaplan et al. 2000, p. 171). Humans also use a wider range of strategies and techniques to capture prey than other animals (Kaplan et al. 2000). Similarly, efficient exploitation of plant resources requires the ability to identify, locate, and process dozens of plant species, and to predict availability and abundance based on weather and growing conditions, while the use of food storage requires knowledge of preservation techniques such as drying and smoking (Scalise Sugiyama 2011).

Another measure of extractive complexity is children's ability to forage for themselves. Although, in some habitats and/or seasons, children are able to acquire considerable quantities of collected resources, data indicate that children cannot easily acquire extracted or hunted resources, or cannot acquire them in sufficient quantities to be self-supporting (Scalise Sugiyama 2011). In a comparison of three forager populations, Kaplan et al. (2000) found that difficulty of acquisition predicts the age profile of food production: High return rates for extracted and hunted resources are not reached until early-to-mid adulthood. In a range of biomes, peak foraging efficiency is not reached before the age of sexual maturity (Scalise Sugiyama 2011), and juvenile consumption exceeds production until the late teens or beyond (Kaplan and Robson 2002). If human extractive techniques were cognitively undemanding, we would expect children to become self-supporting much earlier in the lifespan.

Moreover, studies indicate that children's foraging ability is sharply limited by ecological constraints (Scalise Sugiyama 2011). High juvenile return rates tend to be associated with safe, easy-to-navigate environments or with foraging while accompanied by adults, which relieves children of the tasks of predator evasion, avoidance of environmental hazards, and wayfinding (Scalise

Sugiyama 2011). Research on children's foraging suggests that, in at least some habitats, skills auxiliary to foraging are not mastered until mid-to-late adolescence (Scalise Sugiyama 2011). Additionally, as Kaplan et al. (2000) note, humans exploit much larger territories (200 km² or more) than chimpanzees (10 km²), which may compound the cognitive demands of spatial reasoning. Evidence also points to qualitative differences between chimpanzee and human foraging cognition: Chimpanzees are capable of memorizing the location of potential food sources and using mental maps to locate them later; however, they appear to be incapable of finding food patches without prior knowledge of their existence (Wrangham 1977). Humans, in contrast, can predict probable locations of food resources based on the properties of known locations (Mithen 1996).

The foraging niche poses social challenges as well: Forager subsistence practices are dependent on the use of complex cooperative strategies. Food sharing is a case in point. Human life history is characterized by both inter- and intragenerational food transfers (Kaplan et al. 2000). The prolonged juvenile period, for example, is made possible by extensive male provisioning of females and offspring (Kaplan et al. 2000). In many forager societies, foraging risk is managed by the sharing of subsistence information: For instance, hunters add to their store of knowledge by observing other males and listening to them recount their hunting experiences (Scalise Sugiyama 2011). Similarly, subsistence stress is mitigated by within- and between-group exchange networks that mandate resource sharing among members, including territory (e.g., Minc 1986) and information regarding resource availability and location (Heffley 1981). Additionally, cooperative hunting is widely used to increase the chances of acquiring game or to acquire game in larger quantities (e.g., game drives; Anell 1969). And across forager societies, oral tradition is used to inculcate social norms prescribing generosity and industriousness, and proscribing selfishness and sloth (Scalise Sugiyama 2011). Food sharing is also used to manage the risk of starvation during periods of illness or

injury (Gurven et al. 2000; Sugiyama and Chacon 2000). To effect these strategies, humans must acquire, process, integrate, store, and retrieve large quantities of social information. This task is compounded by the fact that social relationships are in constant flux, which means that individuals must continually update their mental map of the social environment.

However, the physical environment is in continual flux as well: Animals move, hide, and migrate; plants grow, ripen, and die; and weather and topography change with the seasons, cataclysmic events, and long-term fluctuations. Thus, occupation of the foraging niche depends on access to both ecological and social information. This makes it difficult to dismiss the ecological hypothesis out of hand. Dunbar suggests that one way to disentangle these selection pressures is to examine the content of conversation. If language evolved in response to the demands of cultivating and maintaining alliances, he reasons, we would expect conversation to be devoted primarily to the exchange of social information.

Studies in modern industrialized societies indicate that this may be the case: Roughly two thirds of conversation time is dedicated to the transmission of social information (Dunbar 1996). The majority (65 %) of this information consists of social experiences, half of which concern the speaker or his/her audience and half of which concern individuals who are not present (Dunbar 1996, p. 176). Wiessner (2014) found a similar proportion of social information in the daytime conversations of !Kung foragers: 31 % of conversation addressed economic matters (e.g., foraging plans, resource availability, hunting strategies, technology), while the remainder focused on complaints and criticisms of behavior (34 %), joking (16 %), land rights (9 %), stories (6 %), and interethnic relations (4 %). Interestingly, nighttime conversation was heavily biased toward storytelling (81 %). Although Wiessner claims that these stories did not contain much environmental information, Biesele notes that “much subsidiary information about the behavior of animals, the habitats of plants, and the customs of humans regarding them is tucked within” !Kung stories,

and “appears to be utilized later as part of a general fund of knowledge” (1993, p. 45). Tellingly, the stories in Wiessner’s study “almost always described what people were eating at the time of the event” (2014, p. 14029). The blending of social and economic information in forager storytelling suggests that conversational accounts of “social experiences” might encode ecological information, and that using content analysis to disentangle the selection pressures involved in language evolution is not a straightforward matter. Moreover, given the substantive proportion of forager conversation devoted to economic topics, the higher proportion of social information does not rule out the possibility that language evolved in part to meet the demands of complex extraction. The widespread use of storytelling by foragers to transmit ecological information (Scalise Sugiyama 2011) supports this claim, as does the use of vocalizations by nonhuman primates to communicate both social and ecological information. For example, vervets use different calls depending on whether they are approaching a dominant animal or a subordinate one, yet also use calls specialized for the ecological threat of predation: One type is used for terrestrial predators such as leopards, another type is used for aerial predators such as eagles, and yet another type is used for snakes (Dunbar 1996).

Conclusion

The functionally heterogeneous nature of the human mind (Barrett et al. 2007) argues against a monolithic explanation for brain expansion. As with the rest of the body, the brain was subject to different selection pressures at different times over the course of hominid evolution. Similarly, the use of complex extraction techniques that include cooperation argues against a content-centered model of language evolution. The use of language to transmit both ecological and social information suggests that there was selection not for the communication of a specific type of content, but for the communication of mental representations (Tooby and DeVore 1987; Barrett

et al. 2007). This view is in keeping with evidence that the mind has evolved intuitive ontological categories: domain-specific learning rules and inference systems for reasoning about different types of entities in the world, such as artifacts, natural kinds, and agents (Boyer and Barrett 2005). The existence of such mechanisms attests to the evolutionary importance of the information domains they serve. If it is beneficial to store information from all of these domains, it stands to reason that it is beneficial to share information from all of these domains.

Two time-tested models that take a holistic approach to hominid brain expansion are the cognitive niche hypothesis and the embodied capital hypothesis. The former focuses on mapping the design of the mind, arguing that the cognitive abilities that appear to be unique to (or more highly developed in) humans are largely dedicated to the generation, extraction, storage, organization, integration, and exchange of information (Tooby and DeVore 1987; Barrett et al. 2007). The latter focuses on mapping human life history evolution, arguing that the increase in information-processing capacities coevolved with long lifespan, prolonged juvenility, and inter- and intragenerational resource transfers as hominids moved into a skill- and knowledge-intensive feeding niche (Kaplan et al. 2000). For over thirty years, these cross-disciplinary models have provided a structurally sound foundation for the generation and testing of hypotheses regarding the ecological and social selection pressures posed by ancestral human environments, suggesting that an integrated approach to hominid brain expansion and language evolution is the surest path forward.

Definition

Gossip is a way of communicating our thoughts about other people: thoughts which can be negative or positive. Indirect reciprocity is helping someone, with the belief the favor will be later returned by a third party. Gossip and indirect reciprocity are linked together through cooperation, trust, and reputation.

Introduction

Evolutionary perspectives have had trouble pinpointing why cooperation among strangers with an uncertain future of meeting again still occurred. Richard Alexander coined the term “indirect reciprocity” to explain why these instances kept happening among individuals (Nowak and Sigmund 1998). Indirect reciprocity is when a person helps someone with the expectation of the favor being returned later from a third person. Alexander (1987) asserted indirect reciprocity involves reputation and status, the underlying theme being people care about what others have to say about them. Since indirect reciprocity takes place among multiple people, gossip, cooperation, and trust are all valued.

Individuals gain such things as reputation, status, and trust through gossip. Gossip is what

people say about others when they are not present. We tend to think of gossip in a negative manner, but positive outcomes can result from gossip and indirect reciprocity. For example, avoiding negative gossip and its consequences can foster cooperation and other prosocial behaviors (Feinberg et al. 2014). When people gossip in a positive way (i.e., describing a positive attribute), they can build trust among peers, which can result in cooperation, reciprocity, and reputation (Sommerfeld et al. 2008). When someone gossips in a negative way, they tend to be ostracized, and later, they will be compelled to cooperate more with the group (Feinberg et al. 2014). Very simply, people like those who do good and say good. Those who cooperate and do good acts will later receive indirect benefits from third parties (Wu et al. 2016). Thus, people gain indirect reciprocity through reputation. Since indirect reciprocity is based on reputation, people need to gain trust and reputation through cooperation and gossip (Nowak and Sigmund 2005).

Nowak and Sigmund (2005) presented a model of indirect reciprocity based on image scoring. During indirect reciprocity games, participants were given “scores,” and other members would view their scores. This perspective helps study the role of observers assessing the reputation of donating players (Mohtashemi and Mui 2003). It was later argued that Nowak and Sigmund’s model did not fully explain indirect reciprocity. Leimar and Hammerstein (2001) argued their model failed to represent the true strategy interest of an individual. They proposed individuals could be interested in a “good standing” strategy. People want to be good, and they also want to show others they are good.

Other indirect reciprocity games like the prisoner’s dilemma and public good games provide a better understanding of indirect reciprocity. Nowak and Sigmund (2005) summarize players are willing to contribute to public goods but eventually stop their willingness after a few rounds. This is changed when participants understand their reputation will be communicated among other players. Again, gossip takes place in an indirect reciprocity game, and this is important to participants because if they are not cooperating,

their reputation could be at stake. The result could be ostracism from the group.

Conclusion

Gossip and indirect reciprocity are beneficial to people who are willing to cooperate with others. If not, people will be ostracized from their group, but it has been explained that individuals who are ostracized will be more compelled to cooperate as a result (Feinberg et al. 2014). Different models have explained why people are willing to cooperate to gain indirect reciprocity, trust, and reputation. People who gossip in a positive way and are willing to cooperate and show trust can gain reputation and later be benefited from indirect reciprocity. In the end, if you do good for someone, eventually, that good will come full circle.

Forms of social and verbal aggression

Introduction

Folk wisdom suggests that women engage in gossip and spreading of rumors more than men do. The evidence however is unclear, with adolescence being the only stage of life when females seem most likely to engage in gossip and spreading of rumors more than males (Archer 2004). However, the extreme consequence of gossip and spreading of rumors is social exclusion. Theory and evidence suggest that girls and women

may employ social exclusion of unrelated same-sex peers more than boys and men do (Benenson 2013).

The Functions of Gossip and Rumors

Gossip and spreading of rumors constitute an aggressive strategy that allows the perpetrator to manipulate the reputation, status, and relationships of a target. Because innuendo is frequently utilized, gossip and spreading of rumors constitute a powerful form of aggression unconstrained by objective evidence. Further, because the target typically is not present, harm is inflicted on a target with no opportunity for self-defense. A target's reputation therefore can be destroyed by dissemination of accurate or false information. Because the target has no possibility of providing a differing perspective, situating actions with a broader context, or recruiting the support of allies, the perpetrator is free to shape the impression of the target without any verification of facts. The requisite absence of the target means that by definition, the target has been excluded, at least temporarily.

In addition to harming the reputation of the target, gossip and spreading of rumors can also damage or sever the bonds between the target and his or her allies. By persuading listeners to believe the validity of defamatory information, the perpetrator can indirectly or directly suggest that social connections to the target be weakened or dissolved. If the perpetrator's claims appear serious enough, then the listeners jointly can decide to exclude the target from the social milieu permanently. Once a target's reputation has been maligned severely enough, listeners typically do not contradict the perpetrator, so as to avoid tarnishing their own reputations thereby risking their own social ties.

Theoretical Advantages of Social Exclusion to Females

Social exclusion likely is utilized most frequently when the perpetrators derive no benefit from

cooperating with the target and may even benefit from the target's absence. This requires an ecology in which individuals are not cooperating to obtain resources or more generally engaging in joint enterprises or in which specific individuals do not appear capable of contributing to the common goal. Societal institutions which require cooperation cannot afford to exclude valuable allies, especially energetic, reliable, skilled, and social individuals.

Because cross-culturally men typically have cooperated with unrelated same-sex peers during lethal inter-group aggression as well as in numerous community institutions, including governments, religious organizations, and other societal institutions (Baumeister 2010; Wrangham and Peterson 1996), social exclusion of unrelated same-sex peers may be particularly damaging to men's interests. Inter-group contests typically are won through strength in numbers, so exclusion can be beneficial only when extra individuals cannot make any contribution to the common good.

Women, in contrast, cooperate more with kin spouses, and affines who provide critical assistance with child care. These individuals share genetic investment in a woman's children, so benefit from investing in ensuring their well-being. Women then would be expected to preserve relationships with individuals who provide assistance with child care and who share genetic investment in her children. Unlike unrelated men who jointly defend and aggress against external groups, the presence of unrelated women does not provide the same benefit. Rather, unrelated women often deplete social and material resources for a woman and her children.

A classic example is when adolescent girls and women compete for long-term mates. In monogamous and polygynous communities, a woman must best other women to form a long-term pair bond. A husband who invests in her and their children will greatly increase a woman's probabilities of survival and reproductive success (Rucas et al. 2012) and of her children's thriving in modern societies (Amato and Gilbreth 1999). Maintenance of the pair bond further requires repelling additional

women. In polygynous communities, unrelated women compete continuously for material resources and emotional investment of their common husband (Jankowiak et al. 2005). Regardless of type of pair bond, a woman and her children benefit from reducing the presence of other women. Females' preference for interaction with one other individual at a time begins in early childhood where they interact in more exclusive one-on-one same-sex friendships compared to males who prefer larger, more interconnected groups of same-sex friends (Fabes et al. 2003).

Gossip and rumors that result in social exclusion constitute a valuable aggressive strategy for females for an additional reason: Social exclusion is an unusually safe form of aggression. Because females' continued investment in children exerts a greater effect on future reproductive success compared to males' investment, females must take greater care to protect their well-being (Campbell 1999). Responsibility for protection of children from proximate threats also typically falls to mothers. Reducing risk therefore is more critical for females than males. By requiring allies and outnumbering a lone target, social exclusion diminishes the probabilities of both immediate physical injury and future retaliation. Social exclusion thereby provides a means of eliminating rivals without endangering a woman or her children.

Because social exclusion often may be carried out by unrelated females, girls and women do benefit from maintaining a close bond with one or two same-sex friends whom they trust. Together, females may select a target and employ gossip and rumors, and perhaps social exclusion, to expel a rival. At the same time, a girl or woman is protected from social exclusion simply by the presence of a close, loyal friend. In order to reduce the probability of retaliation, social exclusion typically is directed against lone targets. Thus, same-sex friendship is extremely important to females in middle childhood and early adolescence before they form a pair bond (Benenson 2013). In the presence of kin husbands, or affines, however, the role of a close female friend is diminished.

Conclusion

In conclusion, gossip and rumors likely are employed as aggressive strategies by both sexes but may be utilized by females more than males in adolescence when human females typically form pair bonds. Social exclusion may result when gossip and rumors lead to severe damage to an individual's reputation and hence promote the severing of ties to the target. Females benefit more than males from social exclusion of unrelated same-sex peers because an exclusive pair bond provides critical social and material resources to a woman and her children, and social exclusion can be safely executed without fear of physical harm.

Definition

Grammar is a combinatorial computational procedure that can generate an infinite number of novel expressions from a finite set of building blocks.

Introduction

Acquiring a language involves learning its grammatical rules that combine the words to create new utterances. The discussions surrounding the acquisition of grammar have so far mainly focused on the relative contributions of children's innate endowment and the environmental input they receive to their success at the language-learning task. It is clear that the cognitive underpinnings of the *ability* to acquire language must be encoded in the human genome, as this ability is unique to humans. Considering that humans acquire different languages depending on their experience, it follows trivially that environmental stimuli also play a role in shaping language development. The real challenge, however, is to figure out which aspects of the grammar – if any – require postulating an innate Universal Grammar that pre-specifies the structural principles of language and which aspects can be constructed in a piecemeal fashion by processing the regularities in the environmental input via domain-general mechanisms, without needing innate language-specific constraints. In what follows, the arguments that have been advanced in favor of both nativist and emergentist/constructivist viewpoints will be introduced.

Innate Principles: Argument from the Poverty of the Stimulus (PoS)

In linguistics, nativists have long advocated that humans' knowledge of the grammar of their language surpasses what they could have reasonably learned by listening to the linguistic input they were exposed to. The ensuing argument, called *argument from the poverty of the stimulus (PoS)*, was that the knowledge of any grammatical principle that lacked evidence in the input had to be

innate. A classical example cited in this context is the *principle of structure-dependency*. Chomsky (1971) has argued that, upon encountering the sentences “The dog in the corner is hungry” and “Is the dog in the corner hungry?,” a speaker could posit two rules to explain how the interrogative sentence was derived from the declarative. First, she could hypothesize that the *leftmost auxiliary* in the declarative sentence was moved to the sentence-initial position to form a question. This would be a *structure-independent* rule, as it relies on linear order. This rule, however, fails to generate the correct interrogative if the declarative is a complex sentence with a relative clause, such as “The dog that is in the corner is hungry.” To derive the correct question in this case, the speaker must hypothesize a rule that relies on the hierarchical structure of the sentence and not on the linear order of the constituents (i.e., a *structure-dependent rule*), such as “move the auxiliary of the main clause to the sentence-initial position.” It was claimed that even 3–5-year-old children never made any errors that would indicate that they were following a structure-independent rule for forming the interrogatives of such sentences, even though they may not have encountered these forms in the speech directed to them. This was thought to show that children possessed the innate knowledge that grammar is structure-dependent (Crain and Nakayama 1987). But it should be noted that a later study by Ambridge et al. (2008) has shown that children do produce interrogative sentences that violate structure-dependency, albeit rarely. These authors contended that the absence of these errors in Crain and Nakayama's study might be related to the near-exclusive use of the auxiliary *is* in their test sentences, with which children are particularly proficient.

Other assumptions that the PoS argument relies on, too, have been called into question in subsequent research. For example, by presenting a simple recurrent network (SRN) with incremental language input, Lewis and Elman (2002) trained it to predict the syntactic category of the next word to come in the sentence. Crucially, the training set did not contain questions with subjects modified by a relative clause (e.g., *Is the boy who is smoking crazy?*), because these were precisely

the structures that might serve as evidence for structure-dependency, which were argued to be missing in the input. Lewis and Elman (2002) demonstrated, however, that the SRN predicted an auxiliary (e.g., *is*) and not a participle (e.g., *smoking*) after “seeing” the relativizer *who*, even in the absence of this direct evidence. As the strings predicted by the SRN conformed to a structure-dependent grammar, it was argued that a structure-dependent grammar could simply be learned by utilizing the stochastic regularities in the input. Later, a study by Real and Christiansen (2005) has shown that simple statistical models that exploit bigram and trigram frequencies (i.e., the co-occurrence statistics for two-word and three-word sequences) that were trained on a set of utterances extracted from a corpus of child-directed speech could also successfully choose structure-dependent interrogatives over ungrammatical interrogatives, because the bigram and trigram frequencies revealed the former to be much more probable. Furthermore, Perfors et al. (2011) have contested the nativist claim that linear grammars were simpler and that children would therefore hypothesize a linear grammar and commit structure-dependency errors if they did not have an innate bias for favoring hierarchical structures. These authors have pointed out that hierarchical grammars sacrifice simplicity in return for “goodness-of-fit” to the data and unlike linear grammars, a hierarchical phrase-structure grammar can also generalize beyond the input (e.g., extrapolating the transformational rules for forming complex interrogatives from simpler structures) – the crucial ability that lies at the heart of the PoS problem. These points run counter to the prediction that a linear grammar would be the first hypothesis for a naive learner to entertain. As a matter of fact, Perfors et al. (2011) showed that a rational Bayesian learner will prefer a hierarchical grammar over a linear one when confronted with actual language input. Similarly, a child learner may also never entertain a linear grammar to begin with, as the input strongly favors a hierarchical grammar. These findings suggest that environmental stimuli may not be too impoverished to support conclusions about structure-dependency, after all.

While this does not preclude the possibility of there being an innate constraint of structure-dependency, it should be remarked that learning accounts are superior to accounts that postulate innate constraints, *ceteris paribus*, as they are more parsimonious. Also, even if humans have an innate bias for adhering to structure-dependency, this bias may not be language-specific. For example, there is evidence that humans perceive and process hierarchical structures in music as well (Koelsch et al. 2013). So, it should be kept in mind that processing structural dependencies may well be a domain-general capacity.

Parameters: Explaining Language Variation

While the universal properties of languages have been designated as *principles* in the generativist tradition, language variation has been dealt with via *parameters*. One example would be the pro-drop or null-subject parameter, which specifies whether a language allows phonologically unrealized subjects. For instance, English is a non-pro-drop language, hence the sentence *John eats an apple* is grammatical, while the string **eats an apple* would be ungrammatical. The Italian counterpart of this string (i.e., *mangia una mela*), however, is grammatical, since Italian allows omitting subject arguments; because the rich inflectional system of Italian can represent the subject via person agreement markers on the verb.

As children have the capacity to acquire any language, they cannot have the correct parameter setting for the language of their community pre-specified at the outset. Rather, children will have to *set* their parameter to the correct value upon encountering relevant evidence in the input, the argument goes. Thus, for an English child who makes subject-omission errors, one example of a “triggering” input that is needed to learn that her language is non-pro-drop may be the presence of semantically vacuous subjects in sentences such as “It rains.” The expletive subject *it* has no purpose other than fulfilling a syntactic requirement, and indeed, in Italian where lexical subjects are

syntactically not required, statements about weather lack a subject, e.g., *piove*, “*rains.” Hyams (1986) has observed that English-speaking children cease to make subject-omission errors at around the same time they start using expletive subjects and concluded that the co-occurrence of these events showed that English-speaking children set their parameter to non-pro-drop on the basis of exposure to this triggering input.

One problem that needs to be tackled, however, is whether “parameter-setting” constitutes an instantaneous and discrete change in a child’s grammar as it tends to be represented in some traditional accounts, or whether it is a continuous and rather unsteady process. As a matter of fact, there is some evidence that young English-speaking children’s argument-omission errors might stem from a sensitivity to the discourse status of arguments. In a sentence-repetition study conducted with 3–4-year-old English-speaking children, Graf et al. (2015) found that children never dropped a subject (or any other constituent, for that matter) when it was used contrastively, e.g., the subjects in the coordinated structure “the pig throws the pillow and the ladybird throws the pillow” were not omitted, but the objects occasionally were. This shows that the relative informativeness of arguments guides children’s syntactic decisions, even though the result may be ungrammatical in the adult language. While children eventually need to overcome this pragmatic bias to attain the adult grammar, this is much more likely to be a gradual process than a rapid and abrupt one.

The same reasoning presumably applies to the acquisition of the canonical word order in one’s language. For example, in head-initial languages such as English, the verb (i.e., the head of a verb phrase) precedes its object (i.e., its complement), while in head-final languages such as Japanese this ordering is reversed. According to a strong interpretation of the parameter-setting account, English-speaking children should converge on the SVO word order of their language at an early age. Objecting to this proposal, Akhtar (1999) has demonstrated that English-speaking children below the age of 4 were willing to use made-up

verbs in sentences with SOV and VSO orders if these verbs had first been introduced in these syntactic frames by the experimenter; though they were more likely to “correct” the word order used by the experimenter, if the verb was familiar. But 4-year-olds predominantly used the SVO structure, with novel and familiar verbs alike. This shows that, while children may have formed an abstract syntactic generalization about the word order of their language by age 4, younger children’s “syntactic” knowledge may still be lexically specific and unproductive; and this conclusion is not compatible with a strong version of a parameter-setting account where a rapid and discrete change happens in the child’s grammar by exposure to input. Thus, as both the non-nativist learning accounts and the parameter-setting account concede, many aspects of language will be learned from the input; but the two lines of thought crucially differ in the quantity of data that will be required for learning, as well as the developmental trajectory in grammar acquisition.

While the principles and parameters account provides an insightful and convenient shorthand for describing the diversity and the putative underlying uniformity of the world’s languages, it is important to note that the linguistic variation that is observed cannot be easily characterized by a handful of binary parameters. In fact, according to the latest estimates, the total number of parameters may amount to thousands; and linguists can hardly agree on what to include in their list of parameters (see Dąbrowska 2015). As far as language acquisition is concerned, it is clear that children revise their hypotheses about the grammar of their language as they encounter new data that may be unexplained by their current hypotheses, yet given the uncertainty surrounding the concept of parameters, it may be best to remain agnostic as to whether this revision process is the same as what nativists have in mind when they refer to parameter-setting.

Conclusion

Knowing the grammar of a language entails knowing its rules. Two central questions in the

field of grammar acquisition are (1) whether any grammatical rules are unlearnable from the input and must therefore be innate and (2) how a child can extract grammatical rules from the input. Current evidence for innate grammatical principles is sparse, and recent research suggests that, even if there arises a need for postulating some innate constraints for learning grammar, it is probable that these constraints will be domain-general rather than language-specific. There is also accumulating evidence that children may draw upon both their cognitive capacity to statistically analyze the language input and their sensitivity to discourse-pragmatic constraints in figuring out the grammatical rules of their language.

Definition

Grammaticalization is the gradual historical process through which grammatical items are created.

Introduction

Grammaticalization is the continuous, gradual, historical process through which languages generate grammatical material like affixes, articles, pronouns, and prepositions. The emergence of grammatical items is not arbitrary or sudden: they are not invented, as terms for new objects and activities often can be, but instead develop from already existing lexical items which are gradually modified to express increasingly

grammatical meanings. This entry describes (1) the specific mechanisms of historical language change which underpin grammaticalization, (2) the major competing explanatory accounts of grammaticalization, (3) the pathways of change along which grammaticalization takes place, and (4) current issues and recent developments in grammaticalization research.

Grammaticalization

Grammatical items have a largely functional role in language, such as marking tense and agreement (e.g. past tense marker *-ed*, plural marker *-s*), identifying participants in the discourse (e.g. *she*, *this*) and indicating the connections and structural relationships between them (e.g. *and*, *with*, *behind*). They can be usefully distinguished from lexical items, which by contrast carry meaningful semantic content (e.g. *tortoise*, *move*, *slow*), and typically describe things, events, and qualities. Lexical items make up the vast majority of the words in every language and are primarily phonologically and syntactically independent; grammatical items, by contrast, are typically syntactically dependent on other items and often phonetically reduced (e.g. the future tense marker *'ll*, the negative particle *n't*). Grammaticalization therefore describes specific changes in the properties of linguistic items from those characteristic of lexical items to those characteristic of grammatical items; through this process, the items themselves become increasingly grammatical (Heine and Kuteva 2002). Importantly, grammaticalization does not happen to single words in isolation, however, but rather to sequences of words or linguistic constructions in specific repeated discourse contexts where they become automated, processed as single chunks of language, and gradually lose their independence of use.

Mechanisms

Grammaticalization has been described as the interaction of four independent but interconnected mechanisms of linguistic change, namely context extension, semantic bleaching, decategorialization, and phonetic erosion (Heine and Kuteva 2002),

which are seen as “different components of the one and same general process [of grammaticalization]” (Heine 2003, p. 579). The canonical example of grammaticalization in the literature is probably the development of the English future construction *be going to* (Heine et al. 1991; Hopper and Traugott 2003; Hoefler and Smith 2009). Historically, this construction had a transparent contentful meaning of MOTION combined with PURPOSE, but it has over time developed additional meanings, firstly of INTENTION and then of PREDICTION, and is, in today’s modern English, most frequently used as a purely grammatical marker of the future tense. Examples of its usage with these three indicative meanings are shown in Ex. (1a–c), which also serve to illustrate the historical progress of the construction from earliest to latest.

- (1) a) I am going to see the bishop.
PURPOSEFUL MOTION
b) I am going to stay here.
INTENTION
c) It is going to rain.
PREDICTION (FUTURE)

Several relevant parallel developments which are characteristic of grammaticalization can be observed in the changing properties of the *be going to* construction shown above. During grammaticalization, meanings frequently change from more specific to more abstract; the loss of semantic content in the construction is often called *desemanticization* or *semantic bleaching* (Heine and Kuteva 2002). The earliest usage in (1a), for instance, has multiple possible interpretations, depending on the context in which it is uttered. In addition to its original meaning of ‘I am moving with the purpose of seeing the bishop’, it can also be interpreted with either of the newer meanings ‘I intend to see the bishop’ and ‘I will see the bishop’. The middle usage in (1b), however, can be interpreted either as ‘I intend to stay here’ or ‘I will stay here’, but not as PURPOSEFUL MOTION, while the most recent construction in (1c), by contrast, can *only* be interpreted with the future meaning ‘it will rain’. In general, earlier constructions will allow newer interpretations, but newer constructions will not allow the older

interpretations. Moreover, the newer, more abstract meanings only gradually supplant the older meanings, which can therefore coexist alongside each other in the appropriate contexts for considerable periods of time, an effect known as *layering* (Hopper and Traugott 2003) or *overlapping* (Heine et al. 1991).

Closely connected to the gradual development of increasingly generic meanings is the phenomenon of *extension*, which describes how the construction is used in increasingly more contexts, becoming more schematic and less syntactically restricted in the process. With the meaning of PURPOSEFUL MOTION, for instance, the original *be going to* construction had two key restrictions: it could be used only with certain main verbs, and only with animate subjects. These restrictions were a direct result of its meaning: it only makes sense to talk about people ‘going to do things’ if they can move independently and with purpose. As the secondary meaning of INTENTION became more prominent, however, it became possible to use the construction also with main verbs like *stay*, when the original interpretation with PURPOSEFUL MOTION would have been impossible, because of the explicit contradiction between the meanings of *go* and *stay*. In fact, it is only when a construction is used in a context where an older meaning is not interpretable that such an extension can be definitively detected, and the change is then said to have been actualized. In modern English, *be going to* has of course been dramatically further extended, as its function has developed into a marker of the future tense, so that there are now no longer any restrictions either on its main verb or its subject: in Ex. (1c), indeed, the meaningless dummy subject *it* is now perfectly acceptable.

Characteristic of the later stages of grammaticalization is *phonetic erosion*, where the construction’s pronunciation is considerably reduced in prominence, and much of its internal phonetic substance can even be lost altogether. Phonetic erosion comes primarily from the construction being processed not as a sequence of individual words, but rather as a single linguistic unit; sequences which are pronounced within a single intonation unit are particularly susceptible to such

so-called chunking (Croft 1995). Chunking inevitably stimulates a loss of salience for the individual words in the construction, and their amalgamation into a single form with its own stress pattern, which is then frequently phonetically reduced as a simple consequence of being used frequently. In modern English, for instance, the future tense “I’m going to” is not usually pronounced as three individual words, but instead as “I’m gonna,” or even as “amna,” with its original form becoming increasingly obscured.

When words become fixed into a construction which is undergoing grammaticalization, semantic bleaching and phonetic erosion are often accompanied by *decategorialization*, where the individual words begin to lose some of the morphosyntactic properties which (used to) mark them as a member of their lexical category, perhaps even losing their status as independent words. The conjunction *while*, for instance, was originally a noun meaning a specific length of time (cf. “we played outside for quite a long while”), but it no longer has the characteristic properties of a noun when it is used as a conjunction introducing a subordinate clause (e.g. “we went out while they were playing”), and so cannot be accompanied by articles, quantifiers, or adjectives in this grammaticalized function.

Most of these interconnected mechanisms of grammaticalization are usually framed in terms of feature loss (e.g. of meaning content, of morphosyntactic properties, and of phonetic substance), but it is important to note that they can also be seen in terms of gaining new functions and meanings in ‘compensation’ for the loss. *While*, for instance, has gained the ability to be used to indicate a temporal relationship between two clauses, and *be going to* can be used in many more contexts as a future tense marker than as a verb signifying PURPOSEFUL MOTION. The development of these additional abstract meanings, and the extension of the contexts in which the constructions can be used, are, of course, some of the main features of grammaticalization.

Explanations

Two competing schools of thought offer different explanations for the fundamental origin of

grammaticalization: one identifies the cognitive process of metaphorical extension as the key mechanism (Heine et al. 1991), the other focuses on the reanalysis of existing linguistic items in appropriate pragmatic contexts (Hopper and Traugott 2003; Traugott and Dasher 2005).

Metaphorical language uses occurs in a situation where an existing linguistic form is used to express a novel meaning which is similar, but not identical, to its conventional, ‘literal’ meaning (Kövecses 2002). Extending the range of a word through metaphor requires creative conceptualization, or the ability to conceptualize one cognitive domain in term of another, to draw analogies between them based on their perceived similarity, and thereby to use a word associated with one meaning to express another meaning. Such creative expression of novel meanings is an extremely powerful linguistic tool, though it is far from exceptional, and indeed metaphorical deviations from conventional meanings are almost ubiquitous in everyday discourse (Deutscher 2005). The human body, for instance, provides an expedient template of reference points which have been used metaphorically in many languages, both to refer to spatially derived parts of a whole, and then, through grammaticalization, to yield spatial prepositions and adverbs, as shown by Ex. (2), which illustrates the development of the Swahili word **-bele* ‘breast’ into a noun ‘front part’ and then adverb ‘in front, ahead.’

(2) Swahili (Heine et al. 1991: 131)

a) *mbele* *ya* *gari* *lake* *ni* *nyeusi*
front of car his is black
‘The front part of his car is black’

b) *gari* *liko* *mbele*
car is front
‘The car is in front/ahead’

Through frequent repetition and memorization, metaphors become gradually entrenched in linguistic knowledge, until they can eventually be used without invoking the analogies needed for their original creation (Langacker 1987). Metaphor does not always lead to grammaticalization, of course, but when it is used to express an abstract domain in terms of a more concrete domain, it naturally results in the layering of

more generic meanings, context expansion, and thus the gradual development of grammatical material.

The second account of grammaticalization places its explanatory emphasis on context-induced reanalyses of linguistic material, which subsequently allow the gradual extension of contexts in which the construction is used (Traugott and Dasher 2005). The *analysis* of a linguistic form is a description of how the form is linked to its meaning; reanalysis occurs when these associative connections change in some way. Reanalysis can affect many different levels of language, from how the parts of the form are mapped to the parts of its meaning (e.g. the word *hamburger* used to be analyzed as “from Hamburg,” i.e. *Hamburg* + *er*, but was later reanalyzed as *ham* + *burger*, yielding novel words such as *cheeseburger* and *beefburger* by analogy), to whether parts of the meaning are better inferred from the context or are explicitly encoded in particular forms. In practice, the complexity of the mappings between individual forms and meanings, and of how a situational context might be conceptualized, means that any two analyses of any two situations will be almost inevitably different, so reanalysis, too, is effectively communicatively ubiquitous (Hoefler and Smith 2009).

On this latter account of grammaticalization, the future meaning of *be going to*, for instance, may have been originally inferred pragmatically from the fact that any purposeful movement to do something automatically implies that the activity will actually take place at some point in the future, meaning that both the (originally encoded) meaning of movement and the (naturally invited) inference of futurity would always be possible interpretations of the construction. After sufficiently frequent similar context-induced reinterpretations, the originally invited inference of futurity can become generalized and eventually turn into the conventional encoded meaning in its own right. Such interpretations, repeatedly inferred and routinely associated with certain expressions, thus yield grammaticalization through conventionalization and context absorption (Traugott and Dasher 2005; Nicolle 2011).

Both these accounts rely on innovative changes in form-meaning mappings, and both provide plausible and persuasive analyses of how these changes can be propagated within linguistic communities. Hoefler and Smith (2009), however, have shown that they can in fact be unified under a single analysis based on the fundamental cognitive mechanisms which underpin ostensive-inferential communication (Sperber and Wilson 1995). In such a model, communication is conceptualized not as the transfer of a coded signal, but rather in terms of a speaker providing evidence for what they are trying to communicate, and a hearer using that evidence to infer the speaker's communicative intentions (Scott-Phillips 2015). Successful communication depends on the specific conversational context, and on the interlocutors' beliefs about what their counterpart understands, or their common ground (Clark 1996). This allows them to determine each other's communicative goals, what information is relevant to those goals in the current context, and thus what the most plausible and relevant interpretation of the communicative episode should be. Both the metaphor and reanalysis accounts of grammaticalization fall naturally out of an ostensive-inferential model; the crucial difference between the accounts lies simply in the intentions of the speaker. Metaphor starts with a deliberate speaker-driven innovation which is then subsequently understood and later adopted by the hearer, while reanalysis comes from a (perhaps unintentional) mismatch between the interlocutors, leading to the hearer's inference of a novel meaning (Hoefler and Smith 2009). In both cases, however, grammaticalization is an inevitable by-product of the imprecise, uncertain, and approximate nature of ostensive-inferential communication, which provides both motivation and means for the use of concrete, accessible forms to express and be interpreted as more abstract, more grammatical meanings.

Pathways

In modern English, *be going to* is increasingly frequently used to express the future tense, and may be on the way to usurping *will* as the main marker of this grammatical function. Such a

replacement would, if fully realized, potentially mark the final chapter in the grammaticalization of *will* itself in English, from its origins in a normal verb meaning DESIRE. Bybee (2015) describes how, in Old English, the verb *willan* could already be used in several different constructions with different meanings, as in Ex. (3). It was used with a direct object to mean WANT SOMETHING (3a), and with the infinitive of another verb to mean INTEND TO DO SOMETHING (3b).

- 3) a) *Ne drincð nan man eald win,*
not drinks no man old wine,
& wylle sona þæt niwe.
and will at-once the new
'No man drinks old wine and immediately
wants some new (wine).'

(1000 WS Gospels: Luke)

- b) *Ic wille mid flōde folc ācwellan.*
I will with flood people to.kill
'I intend to kill the people with a flood.' (1296
Genesis)

(after Bybee 2015, p.118)

Throughout Middle English, the construction with the infinitive in (3b) became much more frequently used than the direct object construction, and by Shakespeare's time the meaning of *will* had expanded to include first INTENTION, then later WILLINGNESS and PREDICTION. When expressing the future tense, the construction then began to be represented in writing by contracted spellings (e.g. I'll, he'll), indicating both its amalgamation into a single linguistic unit, and its subsequent phonetic reduction (see subsection ► "Mechanisms"). English therefore currently has two different grammaticalized markers for the future tense, one which originated in a verb of volition and one in a verb of movement.

A third common source of future tense markers is exemplified in Western Romance languages like French and Spanish, where the basic future tense developed from an original Latin construction made up of a form of *habēre* "to have, hold" following an infinitive. This construction's meaning changed from its original OBLIGATION through INTENTION and then PREDICTION, and the forms of the verb *habēre* were correspondingly reduced over time, via the now familiar processes of

context extension and phonetic reduction, eventually becoming suffixes bound to the main verb in the synthetic future tenses like French *chanter-ai* and Spanish *cantar-é* (both meaning “I will sing”).

Importantly, these three sources of future tense markers are neither exceptional nor restricted geographically to Western Europe, rather they recur in multiple languages all over the world: for instance, those deriving from movement verbs are found in languages as diverse as Bari, Sotho, Margi, Klao, Tzotzil, and Tamil; those deriving from verbs of volition in Modern Greek, Chinese, Swahili, and Inuit languages; and those deriving from obligation in Basque and Danish as well as the Romance languages mentioned above (Heine and Kuteva 2002; Bybee 2015). From these different original sources, the constructions all extend their meanings in intriguingly similar ways, first encompassing INTENTION and then PREDICTION, so that a general grammaticalization pathway of semantic change can be abstracted as follows:

- (4) VOLITION/OBLIGATION/MOUMENT TOWARDS >
INTENTION > PREDICTION (FUTURE)
(after Bybee 2015, p.123)

The formal morphosyntactic properties of constructions undergoing grammaticalization have also been frequently visualized as a similar continuum, or *cline*, of linguistic material, with independent lexical items at one end and bound grammatical affixes at the other, as in Ex. (5). The process of grammaticalization can then be considered as any movement of a linguistic item from left to right along the cline.

- (5) content item > grammatical word > clitic >
inflectional affix (> zero)
(Hopper and Traugott 2003, p.7)

Large-scale cross-linguistic analysis of many attested examples of grammaticalization (Heine and Kuteva 2002) have shown a surprisingly large degree of consistency in the pathways from which grammatical material tends to be derived. The grammatical expression of tense and aspect,

for instance, develops in similar ways in unconnected and unrelated languages. Ex. (4) has already illustrated the main sources of future tense markers, while Ex. (6) shows common examples of the development of past tense markers, which tend to derive from a different, but still restricted, set of sources:

- (6) RESULTATIVE/MOUMENT FROM/FINISH >
ANTERIOR > PERFECTIVE > PAST
(after Bybee 2015, p.143)

Similar pathways have been discovered and catalogued for a large number of grammatical distinctions found in languages across the world (Heine and Kuteva 2002). As mentioned above, the human body is one particularly pervasive source of cross-linguistic grammaticalization, with its salient parts being repeatedly employed to express spatial relationships by analogy with the usual vertical posture of a human being standing upright: *head* can refer to the space ABOVE something, *foot* to BELOW, *face* or *breast* to FRONT, *back* or *buttocks* to BEHIND, *belly* to INSIDE. Interestingly, a cultural aspect to the sources likely to be used in grammaticalization can be seen in an alternative model of space based on the body of a four-legged animal, which is found predominantly in societies focused on nomadism and pastoralism in East Africa. In languages spoken in these communities, for instance, words meaning *back* and *head* are the source of spatial markers meaning ON and FRONT respectively (Heine et al. 1991). Already grammaticalized items like these spatial markers can become even more grammaticalized through the same processes described in ► “Mechanisms”, developing into strongly grammaticalized material like case markers denoting the roles played by particular nouns in a sentence, or definite articles and relative clause markers indicating wider structural relationships within texts (Heine et al. 1991).

The many common documented pathways of grammaticalization (Heine and Kuteva 2002) have also been used to develop a proposed evolutionary network of grammatical change, linking clusters of commonly recognized grammatical categories into evolutionary layers (Heine and

Kuteva 2007), and suggesting that all major morphosyntactic categories can be ultimately derived from prototype nouns and verbs. Evolutionary linguists have therefore proposed that the earliest human language, often called *protolanguage*, probably contained only basic noun-like and verb-like units (Hurford 2012), and that its gradual complexification into modern language took place through the very same processes and mechanisms of metaphor, reanalysis, entrenchment, and conventionalization which underpin grammaticalization today (Smith 2011).

Issues

Perhaps the most important and persistent criticism of grammaticalization is that it is not necessarily a specific linguistic phenomenon in its own right, but simply a cluster of different mechanisms which appear independently in other kinds of historical language change, and which is therefore undeservedly privileged over other potential clusters (Campbell 2001; Janda 2001). The fundamental aim of grammaticalization theory, however, is to provide explanations of the origins of grammatical material, and it is beyond doubt that the mechanisms described above ► “Mechanisms” are the basis of such explanations. More importantly, these mechanisms are not simply independent processes which fortuitously happen to be clustered together, but they are rather interwoven processes, reliant on each other and connected causally (desemanticization, for instance, leads directly to decategorialization and phonetic erosion), which together yield grammaticalization.

One of the pillars of grammaticalization theory has been that movement along the clines is not only gradual but also unidirectional, i.e. from left to right in Ex. (5). This principle has also been the subject of much robust critical debate (Newmeyer 1998), due largely to the presence of apparent counter-examples such as the *degrammaticalization* of derivational affixes like ‘isms’ and ‘ologies’ or function words such as ‘ups and downs’ into lexical items. In her comprehensive treatment of degrammaticalization, Norde (2009) concludes that although unidirectionality is clearly not sustainable as an exceptionless principle, the restricted nature of the very few exceptions which do occur, in comparison to the massive weight of

evidence showing the development of grammatical material from lexical items, actually lends support to a slightly weakened form of unidirectionality as a strong tendency rather than an inviolable principle.

Other important theoretical issues in research into grammaticalization center around disentangling the extent to which grammaticalization should be differentiated from, or should be considered to include, related linguistic processes such as: (1) *lexicalization*, the creation of semantically contentful words or constructions whose meanings are not (or no longer) predictable from their constituents, such as a “black market” which is neither black nor a market, or “mermaid” which is derived from the Old English words *mere* “sea” and *mægd* “maiden” (Brinton and Traugott 2005); and (2) *pragmaticalization*, the development of new discourse markers and particles like “you know”, which are differentiated from other grammatical material in terms of their purely pragmatic function (Diewald 2011). To a considerable extent, the importance of making and maintaining such distinctions depends on the particularities and assumptions of the linguistic framework in which the explorations are being carried out.

One particularly fruitful framework for the investigation of grammaticalization is that of construction grammar (Langacker 1987; Croft and Cruse 2004), which is singularly compatible with grammaticalization due to its foundation on the twin assumptions of the symbolic and usage-based theses. The symbolic thesis assumes that the fundamental linguistic unit is an association between form and meaning, that all linguistic material, no matter how schematic, is inherently meaningful, and that linguistic knowledge can therefore be modeled as a structured taxonomic network with default attribute inheritance. The usage-based thesis, meanwhile, holds that linguistic knowledge, learning, and change all originate through straightforward inductive abstractions of form-meaning associations from their use in language. Construction grammar therefore allows linguistic innovation to be modeled in terms of an extension from a prototype which overrides its default inheritance, and grammaticalization as a gradual increase in schematicity and productivity

of existing constructions, corresponding to unidirectional movement along a continuum (Gisborne and Patten 2011; Smith and Hoefler 2017).

Over recent years, as the field has continued to mature, the focus of grammaticalization research has broadened considerably, both encompassing different linguistic frameworks, including generative approaches, and expanding in a number of new directions to embrace a wide range of fascinating phenomena (Narrog and Heine 2011; Smith et al. 2015). Prominent among these recent developments is the growing interest in the grammaticalization of co-speech gestures in sign languages (Pfau 2015).

Conclusion

Grammar emerges gradually through a complex and subtle interplay of connected mechanisms of historical language change, in which linguistic constructions in specific contexts are repeatedly interpreted with more abstract, functional meanings, fusing their constituent parts together into integrated chunks of language and thereby losing their independence of use. These mechanisms are based in universal fundamental properties of human ostensive-inferential communication, and their repeated application leads to the emergence of consistent pathways of language change, which have shed light not only on where the grammatical material in modern languages comes from but also on the ultimate origins and evolution of human language itself.

Definition

The investment of grandfathers and grandmothers includes different types of support and resources grandparents can target toward their grandchildren. Grandparental investments can include different types of actions, for instance, financial transfers, emotional support, and care. Grandparents can invest in their grandchildren either directly or indirectly via a third party (e.g., via the grandchildren's parents). Typically, grandfathers tend to invest less in their grandchildren than grandmothers, except when comparing paternal grandmother's and maternal grandfather's investment.

Introduction

Grandparents share, on average, 25% of the same genes with their grandchildren, and thus, they can increase their inclusive fitness by investing time and resources in their descendants. Nonetheless, all grandparent types tend not to be in the same position with each other in their relations with grandchildren (Tanskanen and Danielsbacka 2018). Only maternal grandmothers can be 100% certain of their relatedness to grandchildren, while maternal grandfathers (via themselves and their daughters) and paternal grandmothers (via their sons and their children) have one link of uncertain paternity, and paternal grandfathers have two (via themselves and sons and via sons and sons' children). Hence, within the kin lineages, grandmothers are more likely to be genetically related to their descendants compared to grandfathers, meaning that maternal grandmothers are expected to invest more than maternal grandfathers and paternal grandmothers more than paternal grandfathers. This entry considers the role of grandfather investment compared to grandmother investment.

Grandfather and Grandmother Investment

Although the role of grandfathers could have been relatively minor in traditional and historical

populations (Sear and Mace 2008), in contemporary nations, grandfathers are often highly involved in their grandchildren's lives. Indeed, in some circumstances, the investment of grandfathers can approach that of grandmothers. For instance, based on cross-national evidence from Europe, 58% of grandmothers and 49% of grandfathers look after their grandchildren at least occasionally (Hank and Buber 2009). Moreover, in current societies, the investment of both grandmothers and grandfathers is observed to be associated with improved child well-being (Sear and Coall 2011), although it is unclear whether there is a causal association between grandparental investment and child outcomes (Tanskanen and Danielsbacka 2017).

In addition to sex-based differences (i.e., sex effect), grandparental investment varies by lineage, meaning that maternal grandmothers usually invest the most, followed by maternal grandfathers, then paternal grandmothers, and, finally, paternal grandfathers (Coall and Hertwig 2010; Euler 2011). Among evolutionary scientists, the most important explanation for this biased grandparental investment pattern is based on paternity uncertainty. However, paternity uncertainty cannot directly explain why maternal grandfathers often invest more than paternal grandmothers.

With regard to preferential investment in more certain kin theory, the amount of grandparental investment changes according to the availability of other "investment options" (Laham et al. 2005). If grandmothers and grandfathers have grandchildren via both daughters and sons, they are expected to invest more in their daughter's children compared to their son's children. If grandchildren via daughters do not exist, grandparents are expected to invest more in grandchildren via sons. Often, maternal grandfathers may invest more than paternal grandmothers because the latter typically have more certain investment options (i.e., grandchildren via daughters). If more certain investment options are unavailable, maternal grandfather and paternal grandmother should invest equally in their grandchildren. A previous study including over 22,000 European grandparents provided evidence

in support of the preferential investment theory (Danielsbacka et al. 2011).

Conclusions

In recent decades, there has been increasing academic interest in the grandparental role in human families. However, an obvious limitation in many of these studies is that older men have often been ignored and, in practice, "grandparents" have been used as a synonym for "grandmothers" (Coall et al. 2016). Although grandmothers are known to invest more time and resources in grandchildren than grandfathers, the role of grandfathers is far from negligible. Thus, when one considers grandparental investment, it is important to consider also the role of grandfathers.

Grandmother Hypothesis

Postmenopausal altruism

Definition

The grandmother hypothesis is a proposed solution to the evolutionary puzzle of midlife menopause and postmenopausal longevity in several mammal species, whereby postmenopausal females confer greater alloparental care to their kin than would be possible if they continued ovulating or died following menopause.

Introduction

The grandmother hypothesis proposes that the function of postmenopausal (i.e.,

postreproductive) life in females is to provide alloparental care to kin. The hypothesis is invoked to explain not only why senescence and menopause occur and why much of female life is spent in an infertile state but also why post-reproductive females provide especially high amounts of investment to the members of their kin group.

Senescence and Menopause

The grandmother hypothesis was developed as a solution to the apparent puzzle of menopause as observed in humans and other species. Menopause is best defined as the permanent, non-pathologic, age-related cessation of ovulation that occurs long before death (Walker and Hurdon 2008), in other words, when the female ceases to produce egg cells or ova. Nonhuman species that are believed to experience menopause include chimpanzees, macaques, baboons, killer whales, dolphins, and pilot whales. Females in several other species, including dogs, elephants, and laboratory rats and mice, experience rapid declines in ovulatory consistency in the years leading up to their death, reducing their fertility but not eliminating it. It remains controversial as to whether the captive lifestyle contributes to the appearance of menopause and allows animals to reach ages that would be unrealistic in the wild. In general, the challenges of observing wild populations and collecting data on fertility severely limit our understanding of menopause in nonhumans. For each of the primates mentioned, late-life (post “menopausal”) childbirths have been recorded, suggesting that a definite cessation of ovulation is uniquely human. The marine mammals mentioned, however, show consistent and distinct signs of menopause. What constitutes true, humanlike menopause remains controversial.

Senescence is the process of deterioration and dysfunction that occurs as animals age. Theories regarding the evolution of senescence are helpful in describing the potential function of menopause. First, the wear and tear hypothesis suggests that bodies simply degrade over continued use, and the systems that regenerate damaged tissues become less efficient over time and eventually fail after a predictable interval. All female mammals are born

with a fixed number of oocytes (immature ova), usually many thousands more than they will ever need to use in their life (humans enter puberty with 400,000), but these cells deteriorate at a rapid pace across the life span until around age 50 when the last of the oocytes are depleted (Wise et al. 1996). This degradation has been linked with a reduced efficiency at repairing damaged ovarian cells over the life span (Titus et al. 2013). A second possibility is that in ancestral human environments, females did not live long enough to experience menopause, and so the genetics that contribute to menopause have never been exposed to negative selection. Deleterious genetic expressions that would arise in late age could have no history of selection because human life has never consistently extended into late age. This is described by the mutation accumulation hypothesis and antagonistic pleiotropy (Hamilton 1966). Life after menopause could thus be the novel consequence of human environmental conditions and cultures that facilitate unprecedented longevity. A third possibility is that senescence is caused by programmed cellular deaths that accelerate in late age. Telomeres represent a genetic clock, and when they are exhausted apoptosis occurs, a controlled death cycle. Cellular death is known to contribute to aging, and it has been theorized that aging and death serve the function of removing organisms that have already reproduced and accumulated mutations and toxins, while making room for new copies of those organisms. Whether the late-life depletion of oocytes is a controlled process, a process that has never experienced selection, or a consequence of natural wear and tear, the question remains as to why the female body maintains itself and remains healthy for the years following menopause, particularly among humans who can survive well beyond menopause.

Grandmothers and Alloparenting

Alloparenting refers to any behaviors that contribute to the survival and reproduction of offspring who are not your own. Supportive behaviors can include resource provisioning, defense, status enhancement, instruction, etc. The grandmother hypothesis is not limited to the care that older

females can provide to their grandchildren, it also includes care directed toward children, cousins, nieces, nephews, and any local kin that could benefit from the aid of a postmenopausal female. On average, postmenopausal females will benefit more from caring for kin of greater genetic similarity and caring for kin whose genetic relatedness is more assured. More accurately, the genes that promote postmenopausal alloparenting are more likely to reside within more closely related individuals, meaning that the relative success of those genes depends on a preference for providing care to the kin who are most likely to contain them (i.e., assuredly close kin). Confirming these predictions, in late age, female great apes, including humans, show enhanced alloparental care to kin, primarily toward kin who are more directly related and those related through female relatives (Coall and Hertwig 2010). The reason that a female will favor kin who is related to them through a female relative (e.g., a daughter's son rather than a son's son or a sister's son rather than a brother's son) is that she can be certain that the individual is indeed her kin. In the case of a son's child, for example, the grandmother cannot be certain that the child is the product of her son's sexual efforts, just as he cannot be certain that he is the father in the way that the mother can be certain that she is the mother (for the father, this is referred to as paternity uncertainty and is a natural consequence of internal fertilization). Cross-cultural research demonstrates that maternal grandmothers tend to invest the most, followed by maternal grandfathers, followed by paternal grandmothers, and finally paternal grandfathers (Bishop et al. 2009). This investment tends to flow most strongly toward offspring who show the highest likelihood of surviving and reproducing, i.e., more attractive, healthier, and higher status children (Leek and Smith 1991). In general, evolutionary theory predicts that investments made into offspring who can best capitalize on investments will be favored. Thus, depending on the context, grandparents can be expected to invest more heavily into male or female kin, as well.

Following menopause, female humans show enhanced investment into kin. There is limited evidence that this investment improves outcomes for children in industrialized societies (Coall and

Hertwig 2010; Hawkes 2004), and stronger evidence that child life expectancy in non-industrialized societies is improved by the presence of a maternal grandmother (Strassmann and Garrard 2011). While it is clear that human life spans have expanded considerably in the last 10,000 years, with the arrival of agriculture and medicine, research on existing hunter-gatherer tribes suggests that postmenopausal life has been a feature of human life long before the rise of civilization (Gurven and Kaplan 2007). Looking at the human “mortality profile” and modern data on the life spans and infant mortality of hunter-gatherers, Gurven and Kaplan found that humans have a species-typical age of somatic decline, around 70 years. They also show that while hunter-gatherers (and, presumably, ancestral humans) have 30 times the infant mortality of industrial society (driving down their average life spans), survivorship after the age of 15 is only about a decade short of the healthiest cultures on Earth (72 vs. 85 in Japan). If menopause is a product of modern medicine facilitating old age, one would expect to see that the human typical somatic decline occurred at about age 50 and that the modal life span of women in hunter-gatherer societies hovered around 50. These data cast some doubt on the argument that postmenopausal life has not existed long enough to experience selection for enhanced kin alloparenting.

As mentioned, the most important way that grandmothers in hunter-gatherer societies assist their kin is by reducing child mortality, suggesting an interesting relationship between late-life survival and early-life survival. Humans are a remarkably altricial species; we are born in a very vulnerable state, requiring nearly constant attention and resource provisioning (in large part because we are grossly encephalized). Humans are usually considered cooperative breeders, recruiting the aid of local kin and friends to assist with child-rearing, often in a reciprocal manner. It could be suggested that postmenopausal longevity and altriciality coevolved, as having another kin member to provide assistance allows for the evolution of larger, more complex cortex (that requires greater investment). The arguable nonexistence of postmenopausal life among wild populations of primates is weak evidence against

the possibility that more recent human evolution has benefitted from adaptations for increased survivorship and grandparental care beyond oocyte depletion.

Evolutionary Timeline

There are two main ways to interpret the evolutionary timeline of the grandmother hypothesis. The first, original interpretation is that menopause evolved as an adaptation to reduce the risk of late-life pregnancy in women who have (i) accumulated more germ-line mutations, (ii) become less likely to survive childbirth or produce a live child, and (iii) could better benefit from investing in large numbers of kin. In this account, the cessation of ovulation occurs in mid-life to facilitate a new familial role as a grandparent. The second, more recent interpretation is that female life spans expanded beyond the point of natural oocyte depletion and reproductive senescence that would normally coincide with death. In other words, selection favored longer life among women but did not or could not favor later reproductive capacity in women. In this account, the adaptation for grandmothering is the extension of somatic maintenance into late age, regardless of reproductive maintenance. Of course, these explanations are not entirely incompatible (both processes may have contributed), but the debate rests on whether menopause or longevity shows more distinct signs of being designed as adaptations or better resemble by-products or physiological constraints. For example, one could argue that there is a natural constraint on the number of oocytes that can be produced in the embryonic human, leading to a necessary depletion following 50 years of ovulatory cycling, rather than an artificial cap on oocyte production or a controlled process of oocyte destruction. Likewise, one can argue that longevity is a byproduct of the conditions of human life following the invention of tools and cooperation, rather than the accomplishment of adaptations for somatic maintenance. Support for the latter timeline is mounting. First, comparative researchers suggest that our nearest primate relatives show similar menopausal timing, or, at least, begin to show early signs of menopause just prior

to their death of old age (Alvarez 2000). Second, oocyte depletion does not show the characteristics of a controlled process, whereby oocytes are actively limited or destroyed. To the contrary, female reproductive biology appears to strive valiantly to maintain oocyte health. That said, characteristic menopausal shifts in hormone levels do suggest adaptive physiological and psychological adjustments, once oocytes are depleted.

Conclusion

The grandmother hypothesis presents a compelling evolutionary explanation for life after menopause, particularly in human females. As it stands, there is good evidence for the hypothesis that human life spans expanded beyond the limitations of oocyte production and maintenance in order to better facilitate cooperative breeding with kin. Human longevity beyond reproductive senescence does not appear to be a novel feature of human culture (i.e., from the past 10–20,000 years), but it is a novel feature among our closest primate relatives (i.e., from the past 5–10 million years). Interpretations of the grandmother hypothesis differ, and too little is known about nonhuman menopause to make strong claims of human uniqueness, homoplasy, or homology. However, research into marine mammal reproductive cycles may shed light on the life history, social, and physiological characteristics that select for longevity beyond menopause.

Definition

Grandmother hypothesis of menopause claims that human females stop reproducing early in relation to their long lifespan because they can gain more fitness benefits by investing in their children or grandchildren rather than by reproducing themselves. Grandmother hypothesis tries not to explain the evolution of menopause *per se* but rather the evolution of long non-reproductive lifespan of human females.

Introduction

Long nonreproductive lifespan of human females presents an evolutionary puzzle. Evolutionary theory predicts that individuals are programmed to maximize their number of descendants in future generations, meaning that they should reproduce until death. Thus, there should be selection against living well beyond one's fertile years. In contrast to some earlier views, based on current knowledge, menopause is not a feature of humans only, but exists also in some non-primate species, namely dolphins, whales, and perhaps elephants (Euler 2011). However, the long nonreproductive lifespan of human females that can last decades could be a unique feature of human species. This non-reproductive lifespan gives human grandmothers a great opportunity to increase their inclusive fitness by investing resources in their offspring (Lahdenperä et al. 2004). In addition to this "positive" selection pressure, a "negative" selection pressure might also play a role in the evolution of menopause. Negative selection pressure means that reproducing simultaneously with own descendants may cause an intergenerational reproductive conflict that in turn may reduce the survival of both generations' offspring (Lahdenperä et al. 2012). The reproductive conflict can in theory occur between a daughter and a mother or between a daughter-in-law and a mother-in-law.

Empirical Evidence

During the recent decades, the predictions of the grandmother hypothesis have been tested in

several studies. These studies have investigated whether the presence of a grandmother is associated with increased female fertility and improved child survival rates. Studies testing the predictions of grandmother hypothesis have mostly used data from natural fertility and natural mortality populations, including demographic records from historical populations, data from hunter-gatherer populations, and data from modern populations that are living traditionally (Sear and Mace 2008). The empirical studies testing the assumptions of grandmother hypothesis have, however, produced mixed results. While some studies have found support for the grandmother hypothesis, others have not (Coall and Hertwig 2010). Thus, it is not self-evident that the menopause has evolved because it provides inclusive fitness benefits (or prevents negative fitness outcomes) for grandmothers themselves.

The opponents of the grandmother hypothesis have argued that the caring grandmotherhood is a by-product of long infecundity of human lifespan (Coall and Hertwig 2010). This view points out that the long post-reproductive lifespan of human females could have evolved first and caring grandmotherhood only after that. Based on this argument, it could be that during their non-reproductive years grandmothers, who cannot have children of their own, invest resources in their children and grandchildren, because supporting their offspring is better than nothing at all.

Conclusion

The debate continues whether the menopause is an adaptation, by-product of long human age, or something else. Whatever is the truth the grandmothers have often been in the right place at the right time improving parental fertility, grandchild survival, and thus their own inclusive fitness.

Definition

The grandmother hypothesis states that the long post-reproductive life span in human females would have evolved because women were able to gain more fitness by investing in their adult offspring and grand-offspring rather than by reproducing until old age. Because of this fitness benefit, selection would have favored a longer

post-reproductive life span during human evolution.

Introduction

In most animals, reproductive and somatic senescence occurs at the same time as a part of the gradual decline in overall physical condition with age. In few species, however, the reproductive functions show an abrupt deterioration well before other body functions, leading to a total loss of fertility during middle age and subsequent post-reproductive life span of several decades. So far, the most convincing evidence from menopause and long post-reproductive life span comes from a few whale species, namely, killer whales and short-finned pilot whales, and human females whose post-reproductive life span contributes to a significant proportion of their total life span (Ellis et al. 2018).

The paradox of long post-reproductive life span has puzzled evolutionary biologists because it runs against the central presumption of traditional evolutionary theory of individuals trying to maximize their evolutionary fitness during their life span, which usually comes from individuals reproducing until death. In humans, it has been suggested that the long female post-reproductive life span evolved through kin selection and the inclusive fitness benefits gained after menopause by investing in their adult children and grand-offspring (Hawkes et al. 1998).

Hypothesis and Background

The grandmother hypothesis is based on the kin selection theory by William Hamilton (1964) and ideas proposed by George Williams (1957). The kin selection theory explains helping behavior in social species. According to this theory, an individual should help relatives as long as the benefits from helping are greater than the costs, to increase the individual's inclusive fitness and pass their genes to future generations. With kin selection theory, evolutionary biologists have been able to explain many puzzling altruistic behaviors in animals, for instance, the existence of sterile workers

in social insects. Williams (1957) was the first to suggest that menopause was adaptive and beneficial for human females because there are costs involved in continuing to reproduce until old age, and women who cease to reproduce earlier would be able to devote their remaining energy to the care of the living children (often referred to as the “mother hypothesis” or “stopping-early hypothesis”). The costs in old age would be realized as elevated risk of stillbirth or fetal loss for women and higher risk of birth defects for offspring (e.g., chromosomal abnormality). The late born children would also have a greater risk of mother loss, and late births would risk not only the latest child but also previous dependent children, as there is increased risk of mortality associated with late-life pregnancy (Penn and Smith 2007). Therefore, rather than facing the risk of late births and the high cost of rearing infants, it would be more beneficial for women to devote their remaining reproductive effort toward increasing the survival and reproductive success of their own young juvenile and adolescent offspring.

The grandmother hypothesis was first proposed in its current form by anthropologist Kristen Hawkes and her colleagues in the 1990s, who studied Hadza hunter-gatherers of Tanzania. They noticed that postmenopausal grandmothers were important caregivers to their grandchildren, and variation in children’s weight was positively correlated with their grandmother’s foraging time (Hawkes et al. 1997). Hawkes and colleagues formulated the hypothesis to specifically explain the selection for longer life span after menopause while not explaining the evolution of menopause per se (Hawkes et al. 1998; Hawkes 2003). They also suggested that the grandmother hypothesis would explain other traits specific to humans: our late maturity, small size at weaning, and high fertility based on Charnov’s dimensionless assembly rules for mammalian life histories (Hawkes et al. 1998). This hypothesis was proposed to mainly concern daughters having helping mothers because mothers and daughters face similar trade-offs, whereas sons must invest in mating competition (Hawkes et al. 1995). Additionally, the genetic relatedness to the grandmother is uncertain when it is a question of the son’s child, and the benefits to the grandmother’s fitness with regard

to helping her son and daughter-in-law reproduce are much more uncertain than in the case of the grandmother’s own daughter (Hawkes et al. 1998).

The grandmother hypothesis was originally associated especially to mother-child food sharing. According to Hawkes et al. (1998), older women could provide for their daughter’s weaned offspring, thereby enhancing the children’s survivorship and allowing their daughters to produce more children sooner. Also, the helping grandmother may lower her daughter’s age at which she begins to reproduce, the inter-birth intervals might become shorter, and hence the daughter could produce more children with increased survival. Consequently, the daughter’s fitness increases, as well as the grandmother’s own inclusive fitness. However, food sharing is not the only contribution of postmenopausal women to their daughter’s reproductive success. Grandmothers are often providers of childcare and shelter in addition to contributors toward food gathering and processing (Coall and Hertwig 2010). Any economic or social support provided by grandmothers could increase their daughter’s lifetime reproductive success as well (Volland and Beise 2002).

Evidence

The grandmother hypothesis has gained support from many populations worldwide; however, some studies have shown controversial results. The hypothesis has been tested, for the most part, among populations with natural fertility and mortality, such as historical or hunter-gatherer human populations, but there are also studies in modern human populations living in traditional settings or in modern Western populations. In natural fertility populations, grandmother help is often associated with increased survival of the grandchildren, enhancing their growth or increasing the offspring’s reproductive success (Hawkes et al. 1997; Lahdenperä et al. 2004; Sear and Mace 2008; Volland et al. 2005). In modern populations, grandmothers may have improved their grandchildren’s well-being, which is measured by cognitive skills, health, educational

achievements, or socio-emotional measures (Sear and Coall 2011; Tanskanen and Danielsbacka 2017, 2018). Several studies have indicated that the maternal grandmother could be more beneficial to grandchildren than the paternal grandmother (Sear and Mace 2008). Additionally, grandmothers are often most beneficial during the most sensitive periods during child development, for example, during weaning (Lahdenperä et al. 2004; Sear and Mace 2008). However, in contrast to these studies on helpful grandmothers, some studies have not found evidence for the prediction that grandmothers benefit their children or even have adverse effects on their grandchildren (Voland et al. 2005). Similarly, as some fitness calculations have found, the grandmaternal helping effects appear to be enough to select for longer post-reproductive life span in human females; some have found the grandmaternal helping effects to be too weak alone to select for longer life span after menopause (Kim et al. 2012; Lahdenperä et al. 2012).

Recently, it has been suggested that other animals should be studied in different taxa with or without menopause and long post-reproductive life span to compare with humans and enhance our understanding of the evolution and selection pressures on post-reproductive life span and long life in general (Croft et al. 2015). Indeed, several species without menopause also show evidence of grandmaternal help but the potential fitness benefit of this behavior remains unclear. In few animals, the grandmothers have had measurable fitness benefits from helping. For instance, the presence of grandmothers was associated with increased survival of grand-offspring in vervet monkeys, Japanese macaques, and Asian elephants (Fairbanks and McGuire 1986; Pavelka et al. 2002; Lahdenperä et al. 2016).

Other Hypotheses for Human Menopause, Post-Reproductive Life Span, and Longevity

Several other hypotheses have been formulated to explain the occurrence of menopause and post-menopausal life span in women. Some researchers have proposed that these traits result from a

physiological trade-off favoring efficient reproduction early in the fertile part of life (Wood et al. 2000, “by-product hypothesis” or “antagonistic pleiotropy hypothesis”), whereas others have suggested that menopause and postmenopausal life span in humans are by-products of recent increases in life span or life expectancies due to improved nourishment, medicine, and hygiene and, thus, are not evolutionarily meaningful (“modern artifact hypothesis”). Such suggestions are, however, not upheld by the current knowledge that prolonged longevity in humans had already evolved in the late Pleistocene epoch (Caspari and Lee 2004) and is, therefore, not a recent phenomenon.

It has also been suggested that female menopause or longevity is a by-product of selection for greater male longevity (Tuljapurkar et al. 2007) or due to a mating preference of older males for younger females (Morton et al. 2013). Consistent with these hypotheses, Kaplan et al. (2000) argued that the high nutritional provisioning of older males to reproductively active women and children could increase male mating success in old age and would have, hence, indirectly resulted in increased longevity in females (“embodied capital hypothesis”). These explanations are, however, unlikely, as selection in one sex would be unlikely to give rise to a greater response in the other sex, given that female life span is on average slightly longer than male’s in nearly all populations worldwide (Møller et al. 2009).

Recently, “reproductive conflict hypothesis” concerning the evolution of menopause (and not the long post-reproductive life span per se) suggested that menopause and the minimal reproductive overlap between generations in humans might be the outcome of reproductive competition between generations (Cant and Johnston 2008). The onset of menopause coincides with the age at which a female can become a grandparent and face reproductive competition from the younger generation. In these circumstances, it would be more beneficial for women to stop reproducing and, instead, help their adult offspring to reproduce. This hypothesis has gained support from some empirical studies in humans and in killer whales (Lahdenperä et al. 2012; Croft et al. 2016). In the preindustrial human population,

grandmothers and daughters-in-law faced high costs when reproducing simultaneously (Lahdenperä et al. 2012). According to some inclusive fitness models, these intergenerational costs together with beneficial grandmother effects could have led to menopause and long subsequent post-reproductive life span in human females (Lahdenperä et al. 2012; Croft et al. 2016).

Conclusion

There is substantial evidence that grandmothers provide significant survival and reproductive benefits to their children and grandchildren in humans and in some other animals. There remains considerable debate in the literature regarding which hypothesis explains the evolution of long post-reproductive life span in females. Potentially, a combination of different hypotheses considering both the cooperation and competition between generations would be the most fruitful approach for explaining the evolution of menopause and prolonged post-reproductive longevity in females.

Grandparental solicitude

Definition

Grandparental investment refers to the various types of care (like solicitude, looking after grandchildren, getting in contact, investing time, and tangible resources) grandparents may provide for their grandoffspring.

Introduction

Evolutionary psychologists assume that grandparenthood is not only a social role (Kahana and

Kahana 1971) but has profound implications for reproductive success (Volland et al. 2005). From birth on, children are highly dependable on their parents and require a great amount of parental investment (Trivers 1972). According to the cooperative breeding hypothesis, substantial child care is provided by helpers other than the biological parents (alloparents; Hrdy 1999). In the EEA (environment of evolutionary adaptedness), two parents would not have been enough to rear highly dependent human children for many years until they have reached adulthood. Humans are therefore characterized by a network of family helpers. Today, however, modern demographic changes affect family relationships considerably. In Western societies, birth rates and conjugal stability decreased and life expectancy increased. State welfare provisions substitute for some kin support in raising children, while female participation in the labor force increases the need for child support (Euler 2011). In this entry, however, we argue that grandparents are still a valuable source for child support.

From an evolutionary point of view, it is important to distinguish between consanguine (genetically related) and non-consanguine grandparents (step-grandparents). First, we focus on consanguine grandparents and explore why they invest at all in their grandchildren. Evolutionary psychologists distinguished the sex of the grandparents, the laterality (maternal or paternal), and the sex of the grandchildren in their analyses and found biased grandparental investment in their grandchildren. We refer to different ultimate (grandmother hypothesis, paternity certainty hypothesis, sex-specific reproductive strategies, preferential investment hypothesis, asymmetric genetic relatedness and sex of grandchild), as well as proximate, explanations (sociostructural explanations, aunt and uncle investment, family ties) to explain differences between the investment of the four grandparents. Finally, we review the empirical evidence with regard to non-consanguine, step-grandparental investment.

Definition and Measurement of Grandparental Investment

Generally defined, investment in offspring increases the offspring's fitness at some fitness opportunity costs to the investor (e.g., Clutton-Brock 1991). Evolutionary theories of animal behavior group investments into three types: calories, risk acceptance, and time (Daly and Wilson 1983). Feeding children is still of prime importance in premodern societies but less important in industrialized societies. Risk acceptance, for example, the question of eating or avoid being eaten, is not the primary survival task for humans. Time, however, probably was (and still is) a limited resource throughout human evolution. The time devoted to a particular grandchild, in terms of contact frequency and duration, is one of the main and direct grandparental investment measures and is easily assessed by paper-and-pencil ratings (Euler and Weitzel 1996). Money spent or gifts for the grandchildren are also often used as direct indicators of grandparental investment (Euler and Michalski 2007).

The disposition to invest in kin is expected to be mediated through emotions, especially through feelings of closeness and nurturance toward children and grandchildren (Smith 1991). One of the most frequently used measures for assessing the emotional closeness between grandparents and grandchildren is a direct rating of the emotional closeness or relationship closeness. This variable also seems to be least influenced by situational factors like residential proximity or individual indicators like the age of the grandchild (Euler 2011). Consequently, studies include ratings of emotional closeness, naming favorite grandparents, or grandparental mourning after a grandchild's death as indirect measures of grandparental investment (Euler and Michalski 2007). Indeed, measures of investment and emotional closeness are found to be highly correlated (Pashos and McBurney 2008).

After defining grandparental investment, the next important question is who to ask in order to measure the extent of grandparental investment.

Adult grandchildren are preferred over grandparents as study participants for the following reasons: (1) Every person has had grandparents, but not everybody is a grandparent; (2) older study participants are more difficult to recruit than younger ones; and (3) if the rating questions imply preferring one grandchildren above the other, norms of impartiality may prevent grandparents from expressing favoritism (Euler 2011).

Different measures of more or less successful grandparental investment have used, including child mortality, birth weight, breastfeeding, infanticide, homicide, abuse, inheritance, and educational investment (Coall and Hertwig 2010).

The evolutionary literature distinguishes grandparents along the lineage (maternal or paternal) and the sex of the grandparent (grandmother or grandfather). One of the most intensively studied questions from an evolutionary perspective is the question which of the four grandparents (maternal grandmother, maternal grandfather, paternal grandmother, and paternal grandfather) invests most in their grandchildren (biased grandparental investment).

Thinking about biased grandparental investment from an evolutionary perspective requires the differentiation between consanguine (genetically related) and non-consanguine (step-) grandparents, because different mechanisms are supposed to be responsible for biased grandparental investment for these two categories of grandparents.

Consanguine Grandparental Investment

Genetic relatedness. The coefficient of relatedness between a consanguine grandparent and a grandchild is estimated as $r = 0.25$ on average. Thus, kin selection theory (Hamilton 1964; Maynard Smith 1964) predicts that grandparents invest in their grandchildren in order to increase their own inclusive fitness. The empirical evidence supports this claim. For example, relationships with step-grandparents are less close than those with biological grandparents (Aldous 1995).

Grandmother hypothesis. Other relatives are also related to oneself by $r = 0.25$, for example, half siblings or aunts/uncles, and are also expected to show some mutual interest in related individuals. What is the special social position of grandparents, as compared to these other relatives, and why do we observe such an early and irreversible cessation of fertility followed by a relatively long postmenopausal life expectancy in humans? Williams (1957) considered the human menopause as an adaptation because the benefit of care for existing children outweighs the cost of further reproduction for mothers. This is also called the prudent mother hypothesis. Hamilton (1966) extended this idea to grandmothers, but he was uncertain whether the menopause was an adaptation in its own right. When considering other species, it turns out that in animal kingdom, menopause is not unique to humans. Evolutionary anthropologist Kristin Hawkes thus argued that not menopause but rather life span after menopause has evolved in women (Hawkes et al. 1998). In this view, grandparenthood has evolved together with human longevity because grandmothers, namely, the maternal grandmothers, were needed as important mothers' family helpers. Hawkes' version of the grandmother hypothesis has become the most popular. There are, however, also evolutionary anthropologists who believe that the grandmother's role as family helper is overestimated in the theory, compared to the importance of male family helpers (Hill and Hurtado 2009). The debate continues in biological anthropology whether menopause is an adaptation, a by-product, or a modern artifact (Voland et al. 2005). Nonetheless, the grandmother hypothesis is currently the most influential theory to explain female longevity beyond menopause, and it raised particular attention to the maternal grandmother's investment in grandchildren. Sear and Mace (2008), for example, investigated the effects of the presence of various kin on child survival in 45 (mostly) natural fertility populations. They found that next to the mother, the maternal grandmother is often, but not always, found to contribute more to a child's survival. In

their study, the presence of the other three grandparents including the paternal grandmother was often found less beneficial for the survival of a grandchild.

Paternity certainty hypothesis. How can the difference between maternal and paternal grandparents be explained? Genetic relatedness predicts, all else equal, the same amount of grandparental investment from all four grandparents. The reproductive lifespan of grandfathers, however, is less restricted than the reproductive lifespan of grandmothers. As men grow older, men can still increase their direct fitness, but menopause restricts the reproductive capacity of women. Thus, the grandmother hypothesis predicts more grandparental investment from grandmothers compared to grandfathers. However, what might be an evolutionary explanation for a greater importance of maternal grandparents compared to paternal? The paternity uncertainty hypothesis claims to explain this difference. Grandparents, as well as parents, are not equal in their maternal and paternal certainty of their descents. The famous old Roman principle “*Mater semper certa est, pater semper incertus est*” (“the mother is always certain, the father is always uncertain”) illustrates this sex difference. If, due to internal gestation, mothers can be 100% certain about their biological relatedness to the child, but fathers not, then this differential certainty applies to grandparents as well. Maternal grandparents should be more certain about their relatedness to their grandchild than paternal grandparents.

However, the same differential uncertainty of grandparents also refers to their children (parents of their grandchildren) as well. Thus, the maternal grandmother (mother’s mother) should have the highest certainty about their grandchild. She is certain about her own child, and due to the maternal certainty, her daughter (the mother of the grandchild) is also certain about her child. The most uncertain grandparent is the paternal grandfather (the father’s father). The paternal grandfather can neither be certain about the genetic relatedness of his son (the father of the grandchild) to his son (grandchild) nor can he be certain about his relatedness to his son. Maternal

grandfathers and paternal grandmothers both share certainty on one link.

Smith (1988, 1991) was the first to investigate biased grandparental investment. He found that grandmothers invest more in their grandchildren than grandfathers and that grandparents invest more in daughters’ children (the maternal lineage) than in sons’ children (the paternal lineage). Thus, the predicted rank order of grandparental investment is maternal grandmother (highest investment), maternal grandfather and paternal grandmother (both moderate investment), and the paternal grandfather (showing the lowest investment).

The paternity uncertainty hypothesis states that only mothers, but not fathers, can be 100% sure about their genetic relatedness to their child. Early studies estimating paternity uncertainty in Western societies showed a level of around 10% paternity uncertainty (Macintyre and Sooman 1991), which would fit very well to the effect sizes of biased grandparental investment found empirically. Newer studies, however, estimated the level of paternity uncertainty to only 1–3%, which is too low as sole explanation of the biased investment (Euler, this volume; Voracek et al. 2008; Wolf et al. 2012). At least three different implications regarding the relationship between paternity certainty and grandparental investment are possible. First, the asymmetric caregiving pattern reflects paternity uncertainty in the environment of evolutionary adaptedness (EEA) rather than the actual, genetically verifiable paternity certainty (Euler and Michalski 2007; McBurney et al. 2002). Second, psychological processes do not necessarily operate with base rate probabilities. Applying signal detection theory (Green and Swets 1966) to the paternity certainty problem, two errors are possible. The father may wrongly assume his child to be his biological child or he may wrongly doubt his paternity. According to error management theory (Haselton and Nettle 2006), whenever the costs of the errors are asymmetric, it is assumed that selection fashions adaptations which are biased toward making the least costly error. In this case it could be very costly to devote all time, energy, and resources to a non-related child. This could

also explain why paternal grandfathers invest the least of all four grandparents although the objective paternity uncertainty rates are relatively low. Third, even if paternity uncertainty is a popular explanation for biased grandparental investment, it may not be sufficient alone.

Sex-specific reproductive strategies. Other authors incorporated sex-specific reproductive strategies into their models of grandparental investment, in order to explain the strong matrilineal bias of kin investment (Euler and Michalski 2007; Euler and Weitzel 1996). In mammals the production of eggs and the internal gestation require higher minimal parental investment in females compared to males (Trivers 1972). In order to maximize genetic replication, females ought to maximize maternal investment and reduce further mating efforts. Males, however, due to their reproductive success through mating with multiple females, ought to reserve resources for further mating effort and not expend all resources on paternal effort.

As a consequence, individuals ought to direct their kin support to where it is needed most, that is, sex – specifically to female kin. Thus, maternal grandparents ought to invest more in their daughters and their daughters' children than paternal grandparents invest in their sons and their sons' children (Euler and Weitzel 1996).

The paternity uncertainty explanation predicts the same amount of investment of the maternal grandfather and the paternal grandmother, as both have one link of paternity uncertainty. The assumption of sex-specific strategies, however, further predicts differences in grandparental investment between the maternal grandfather and the paternal grandmother. Following this reasoning, maternal grandfathers, as they invest in their daughter's children, should invest more than paternal grandmothers, who invest in their sons' children (Euler and Weitzel 1996).

The combined effect of paternity uncertainty and sex-specific reproductive strategies thus predicts the often found pattern of grandparental investment, where the maternal grandmother invests most, followed by the maternal grandfather, the paternal grandmother, and the paternal grandfather (Coall and Hertwig 2010). This

asymmetric pattern of biased grandparental investment cannot be explained away by confounding factors like the age of the grandparents (the maternal grandmother is, on average, the youngest and the paternal grandfather the oldest) or residential distance (Euler and Weitzel 1996; Pashos 2000). Other confounding factors, such as birth order, parent age, and grandchild age, were reported in the literature to play inconsistent roles (Euler and Michalski 2007; Euler 2011).

Preferential investment hypothesis. Sex-specific reproductive strategies might explain why maternal grandfathers invest more in their grandchildren than paternal grandmothers. Laham (2005) proposed an alternative hypothesis for this biased grandparental investment. In their preferential investment hypothesis, they assume that alternative investment outlets, i.e., alternative investment options in matri- or patrilineal grandchildren, might additionally explain the strong matrilineal caregiving bias. The existence of daughters' children should reinforce the matrilineality and therefore the investment of the maternal grandfather over the paternal grandmother, whereas the missing of daughters' children should reinforce the investment in sons' children and hence the role of the paternal grandmother. Laham et al. (2005) found some empirical support for their hypothesis; other studies did not (Euler 2011). Taken together the empirical evidence supporting the preferential investment hypothesis is rather weak.

Asymmetric genetic relatedness and sex of grandchild. Chastil et al. (2006) pointed out that discriminative grandparental investment might be influenced by asymmetric genetic relatedness between grandchildren and maternal and paternal grandparents. DNA constitutes of chromosomes, which are either autosomes or allosomes (the latter are also known as sex chromosomes). Regarding autosomes, all four grandparent types are equally genetically related to their grandchildren, but this is not the case regarding allosomes. Males are heterozygous regarding the allosomes. Thus, paternal (but not maternal) grandparents are not symmetrically related to granddaughters and grandsons with respect to the sex chromosomes. Following this line of reasoning and assuming that

kin helper alleles are located to a significant extent on the sex chromosomes, paternal grandmothers are more closely related to granddaughters than maternal grandmothers. Further, maternal grandmothers and paternal grandfathers are more closely related to grandsons than are maternal grandfathers. Kirchengast and Putz (2016) found that the contact frequency between granddaughters and maternal grandparents is higher than between grandsons and maternal grandparents. However, the contact frequency between paternal grandparents and grandsons was only slightly (and not significant) higher than between paternal grandparents and granddaughters. Further, Chrastil et al. (2006) could not support the sex-chromosome relatedness hypothesis in two large datasets. Taken together the empirical evidence for this hypothesis is also rather weak.

Sociostructural explanations. Genetic relatedness, the grandmother hypothesis, paternity uncertainty, sex-specific reproductive strategies, preferential investment, and asymmetric genetic relatedness are ultimate, culture-independent explanations for biased grandparental investment. To some degree, the preferential investment hypothesis acknowledges structural features of the family (e.g., family size and number of grandchildren), but it is deeply grounded in kin selection mechanisms. Other, non-biological reasons for biased grandparental explanations are typically ignored in the evolutionary literature. As Coall and Hertwig (2011) point out, such non-biological, sociostructural approaches are not necessarily competing to evolutionary explanations; they simply operate on different levels. Besides the evolutionary analysis of the ultimate causes, which focuses the behavioral outcome of evolutionary mechanisms, behavior can also be explained directly by its proximate causes. Sociologists have identified structural forces (e.g., female participation in the labor force), social institutions (e.g., the taxation of bequest), and cultural values (for example family obligations and roles) as relevant factors in grandparental investment (Coall and Hertwig 2011). Regarding cultural values, for example, cross-cultural research on grandparental investment is noteworthy. Most studies on grandparental investment, as

well as in psychological research as a whole, rely on WEIRD (Western, educated, industrialized, rich, and democratic; Henrich et al. 2010) samples. In these modern urban societies, matrilineal-biased grandparental investment is nearly universal. Traditional rural societies, however, often show high levels of patrilateral grandparental investment. In rural Greece, for example, paternal grandparents, especially paternal grandmothers, provide more caregiving than maternal grandparents. Paternal grandparents were found to be the primary source of caregiving also in Iowa among rural farmers (USA) and in China. These results show the cultural variability of grandparental caregiving (Pashos et al. 2016; Strassmann and Garrard 2011).

Aunt and uncle investment. A possible way to study the proximate mechanisms underlying biased grandparental investment are aunts and uncles. First, individuals are related to the same degree to grandparents and aunts/uncles ($r = 0.25$). Second, there is no difference in kin certainty of an aunt and an uncle; brothers and sisters of the parents have the same certainty of relatedness with their sibling's children. Finally, potential confounds like co-residence are usually ruled out. As the grandparents live together as a couple, the grandfathers' investment in grandchildren might be positively affected by the grandmothers, especially in case of the maternal grandfather who often invests more than the paternal grandmother. These considerations together would predict just a laterality bias of more investment from maternal aunt/uncle compared to paternal aunt/uncle. The research, however, found only partially support for this prediction. Maternal aunts and uncles invest more than paternal aunts and uncles, but aunts also invest more in nieces and nephews than uncles do. Thus, the female role of caregiving neglected by the ultimate approaches described so far seems to be a likely candidate for this pattern of results and perhaps also as explanation for biased grandparental investment.

Family ties as explanations. A proximate explanation for the asymmetric kin investment could also be the stronger family ties of women compared to men, which lead to a matrilineal pattern of close female-female relationships.

The quality of the relationship between the caregiver (grandparent, aunt or uncle) and the parents of the caregiving recipient was also found to have an impact on the caregiving for grandchildren and nieces and nephews itself. Especially a good relationship between the maternal grandmother and the mother was found to have a positive effect on maternal grandmothers' caregiving (Danielsbacka et al. 2015; Matthews and Sprey 1985; Pashos 2000; Pashos and McBurney 2008; Steinbach and Henke 1998). Hence, family relationship networks appear to play a major role in kin caregiving (Cherlin and Furstenberg 1994; Lussier et al. 2002). Moreover, the caregivers' relationships to the parents of the caregiving recipients were found to explain caregiving asymmetries among grandparents and aunts and uncles to a great extent (Monserud 2008; Pashos and McBurney 2008).

From an evolutionary point of view, the stronger female family ties explanation, however, does not argue against an evolutionary explanation. The theory could explain the creation of proximate social pathways through which evolutionarily formed mechanisms of kin investment are passed (Pashos and McBurney 2008). In social sciences research on family relationship networks, the intention for kin caregiving is merely seen as a result of the social framework conditions or the so-called female kinkeeping effect. In evolutionary explanations, however, the motivation for kin investment is seen as a biological mechanism, which interacts with the social environment.

Non-consanguine Grandparental Investment

From an evolutionary perspective, consanguine grandchildren are expected to be favored over non-consanguine, for example, stepchildren. Furthermore, there is no differential genetic interest in step-grandchildren, and consequently the investment in grandchildren should not be asymmetric. Empirically for step-grandparents, the universal asymmetric matrilineal caregiving pattern has not been found. However, step-grandparental caregiving can be substantial and was found to be

differential between the four grandparents. In Western societies, the parents' stepfathers and, in particular, the grandmothers' later husbands (whose marriages took place when the parents were already adults) provided more kin investment than the parents' stepmothers and grandfathers' later wives (Pashos et al. 2016). When the biological grandparents were divorced and not widowed before they remarried with the step-grandparent, this effect was even stronger. The biological grandmothers' later husbands seemed to mirror the discrimination of the biological grandmothers in favor of daughters' children (as maternal grandmothers). The greater step-grandchild caregiving by grandmothers' later husbands might be explained by mating effort which induces them to invest in their new wives and wives' families (Pashos et al. 2016). By contrast, the grandfathers' later wives, aka step-grandmothers, might rather tend to invest their resources in their original, biological families (Dench and Ogg 2002). For biological parents of stepparents (which are also called step-grandparents), no such effects were found.

Conclusion

From an evolutionary view, grandparenthood has developed in our evolutionary past and is a significant kin investment supporting families in rearing children. The grandmother hypothesis assumes that grandparenthood has evolved through post-menopausal women.

Empirical research has shown that grandparental investment is not equal between the four grandparents, but biased. Many studies from modern Western societies, anthropological field studies, as well as historical data found larger investment from grandmothers compared to grandfathers, as well as larger investments from maternal compared to paternal grandparents. Different ultimate explanations refer to this matrilineal kin investment bias (see paternity certainty hypothesis, sex-specific reproductive strategies, preferential investment hypothesis, asymmetric genetic relatedness and sex of grandchild above).

Grandparental investment might be also explained by proximate, non-biological

approaches (see sociostructural explanations, aunt and uncle investment, family ties above). For example, cross-cultural research found no support for the matrilineal bias in grandparental investment in patriarchic organized societies. In such societies, grandfathers invest more in their grandchildren than grandmothers (Pashos et al. 2016).

As all explanations regarding consanguine grandparental investment are based more or less on kin selection mechanisms, other explanations for non-consanguine grandparental investment are required. As predicted, consanguine grandparents usually provide more caregiving than non-consanguine step-grandparents. However, also non-consanguine relatives can be important kin investors, especially step-grandfathers who are married to a biological grandmother. A suitable explanation for kin investment of not genetically related grandparents might be mating effort.

As Coall and Hertwig (2011) point out, evolutionary explanations are not necessarily competing with sociostructural approaches; they simply operate on different levels (ultimate vs. proximate). Thus, the joint acknowledgment of ultimate, as well as proximate explanations for consanguine and non-consanguine grandparental investment, is required to gain better insights in understanding grandparental investment in future research.

Definition

Grandparental investment refers to all support that grandparents channel toward their grandchildren. Grandparents can invest in their grandchildren either directly or indirectly via a third party (e.g., via parents). Evolutionary theory claims that the

ultimate reason why grandparental investment exists is because grandparents are genetically related to their grandchildren, and by investing resources in their grandchildren, grandparents can improve their own inclusive fitness. Thus, genetic relatedness is a crucial element behind the evolutionary idea of grandparental investment. Biological grandparents have on average a 25 % chance of having the same genes as their grandchildren.

Introduction

Humans are a cooperative breeding species, meaning that other people besides biological mothers invest large amount of time and resources in children (Hrdy 2009). These allomothers often include the child's father, aunts, uncles, and grandparents. Based on inclusive fitness theory (Hamilton 1964), it is beneficial for these allomothers (e.g., grandparents) to invest in their kin because by doing so they can improve their own inclusive fitness. Due to the assessment of the reproductive value of the receiver, investments are usually predicted to go toward the younger generation. In particular, for post-reproductive grandmothers who cannot have own children anymore, helping their already born offspring in descending line tends to be the most efficient strategy to spreading their genes in future generation. Thus, grandparents should favor and invest in (all else being equal) their children and grandchildren over more distant relatives, older relatives, and non-related friends.

Nonbiological Grandparents

All humans have exactly four biological grandparents either they are alive or not. Due to the increased rates of divorce in parental as well as grandparental generations in Western societies, the proportion of nonbiological grandparents is also increasing. Children can have several types of nonbiological grandparents (Coall et al. 2014; Pashos et al. 2016). For instance, step-grandchildren may appear in the family because

the grandparent himself or herself has divorced and has acquired a new spouse who has grandchildren. The child of a grandparent may also have divorced and remarried with a new spouse who has children, who are thus stepchildren to the grandparent's child (Tanskanen et al. 2014; Westphal et al. 2015). In addition, grandparents or their children may have foster or adopted children. If children are adopted by their parents, they may have up to four living nonbiological grandparents. Obviously, the variety of ways children can have nonbiological grandparents makes the study of nonbiological grandparenthood very complex.

Since to date, there are only few studies concerning the difference between nonbiological and biological grandparental investments. This is the case although several previous studies have shown that in biological relationships parents invest more in their children compared to nonbiological parents (see Anderson 2011 for review). Two previous studies have investigated directly the difference between biological and nonbiological grandparental investments. These both have shown that nonbiological grandparents tend to invest less in grandchildren compared to biological grandparents. Using data from Germany and the USA, Pashos and colleagues (2016) found that step-grandparents invested less and were more distant to grandchildren than biological grandparents. Similarly, Coall and colleagues (2014) showed with data from 11 European countries that biological grandparents more likely looked after their grandchildren in a daily or weekly basis compared to nonbiological grandparents. However, the study by Coall and colleagues (2014) showed that biological grandparents more likely than nonbiological grandparents invest nothing at all in their grandchildren.

All nonbiological (grand)children are not necessarily treated the same way. Due to the variety of ways to one can have nonbiological children and grandchildren, the investment in them might be different. For instance, adopted children may be more desired than stepchildren, because in the case of stepchildren, it is more often a question of mating effort which involves children whereas

adopted children are usually wanted *per se*. Thus the investment made in adopted children may not differ from that made in biological children (Segal et al. 2015). However, in the case of grandparents, the mating effort may increase the investment in step-grandchildren if the remarriage happens in grandparental generation compared to the situation that both grandparents are step-grandparents (i.e., remarriage happens in parental generation) (Pashos et al. 2016).

Usually in situations described above, the non-biological relationship between grandparent and grandchild is well known for everybody involved. There is, however, a possibility that a grandparent may not be genetically related to grandchildren if the father is not the genetic father, through, for instance, infidelity or fertility treatments, and this fact may not be known to the grandparents, parents, and grandchildren involved.

Paternity Uncertainty

In humans, paternity uncertainty may affect the relationship between grandparents and grandchildren (Euler and Weitzel 1996). Because of the paternity uncertainty, human fathers can never be absolutely sure the child is related to them. In contrast, women who give birth to the baby do not meet this problem and can be sure that they really are related to the child. Paternity uncertainty creates an adaptive problem for human males, meaning that it is likely that there are some psychological adaptations regulating the amount of resources males are investing in offspring according to paternity uncertainty. In humans, paternity uncertainty may not influence only potential father's behavior but may also expand to extended kin, namely, grandparents.

In the case of grandparents, paternity uncertainty (also called relationship uncertainty) means that only the maternal grandmothers can be sure that they actually are related to their grandchildren, because they can be certain that both their daughters and their daughter's children are genetically related to them. Maternal grandfathers have one link with paternity uncertainty (via them and their daughters). Also paternal

grandmothers have one kinship link with paternity uncertainty (via their sons and sons' children). Paternal grandfathers are in most uncertain positions, because they may not be related to their sons and their sons may not be related to their children. Thus paternal grandfathers have two links of paternity uncertainty.

Based on paternity uncertainty, grandparents can bias their investment according to relationship certainty. Thus, maternal grandmothers are predicted to invest the most, following maternal grandfathers and paternal grandmothers. Finally, paternal grandfathers are predicted to invest the least. Several studies from contemporary societies investigating several types of grandparental investments (e.g., child care help, financial transfers, and contact frequencies) have shown support for this prediction (see Coall and Hertwig 2010; Euler 2011 for reviews). These results hold even after several potential confounding variables, including geographical distance, grandparental age, and grandchild age, are controlled for.

Sex Chromosome Relatedness

Although biological grandparents share on average 25 % of their genes with grandchildren, this holds only in the case of autosomal relatedness, while the unequal sex chromosome inheritance makes the relation more complicated (Chrastil et al. 2006; Fox et al. 2010; Tanskanen et al. 2011). Girls inherit one X chromosome from their mother and one from father. Their fathers have inherited these sex chromosomes from their own mothers (i.e., the girl's paternal grandmothers), and mothers have inherited them from both own mothers and fathers (these are the girl's maternal grandmother and grandfather). Also boys inherit one sex chromosome from mothers, and it includes genes from both maternal grandmothers and grandfathers. However, boys inherit Y chromosome entirely from their fathers who have inherited it from their fathers (these are the boy's paternal grandfathers). Based on the asymmetrical inheritance of sex chromosomes, paternal grandfathers share more genes with grandsons than granddaughters, and paternal

grandmothers share more genes with granddaughters than grandsons. In addition, paternal grandmothers are more related to granddaughters than maternal grandmothers, while maternal grandmothers are more related to grandsons than paternal grandmothers.

Based on sex chromosome relatedness, it could be expected that grandparents allocate their support according to grandchildren's sex. Previous studies investigating this topic have, however, produced mixed results. Using data from seven traditional populations, Fox and colleagues (2010) found some support the prediction. However, an increasing number of studies using data from contemporary societies have not shown convincing evidence for the sex chromosome relatedness predictions (see Chrastil et al. 2006; Kaptijn et al. 2013; Tanskanen et al. 2011).

Conclusion

Nonbiological grandparenthood is a complex subject to study. Different ways of having nonbiological grandchildren may affect the grandparental investment behavior. Studies comparing the investment of nonbiological and biological grandparents are scarce. Those few studies (Coall et al. 2014; Pashos et al. 2016) that exist implicate that especially intense investments are more often made by biological grandparents than by nonbiological grandparents. As Pashos and colleagues (2016) suggest, in addition to biological relatedness, it is important to separate different types of having nonbiological grandchildren. For some, the investment in grandchildren may be more related to the mating effort than the others which may in some cases generate more investment from nonbiological grandparent than is expected.

The possible effect of the degree of genetic relatedness is related to the grandparental investments through paternity uncertainty and unequal sex chromosome relatedness. One of the most robust result of grandparental studies is that maternal grandmother invests the most following maternal grandfather paternal grandmother and paternal grandfather. This can be explained by

uncertainty in genetic relatedness created by paternity uncertainty. Unequal sex chromosome relatedness would predict different investment according to grandchild sex, but these predictions have not been systemically supported by previous studies.

Although studies have found support for the inclusive fitness theory (Hamilton 1964) showing that greater genetic relatedness is often associated with higher amount of investment among grandparents, there is need for future studies showing in what circumstances socio-ecological factors can override the effect of genetic relatedness. Moreover, in contemporary societies with increased amount of blended families, it is important to compare the possible effect of genetic relatedness to grandparental investment in different family situations more carefully. Finally, longitudinal studies on the topic are needed.

Introduction

Becoming a grandparent can be one of the most jubilating moments in one's life. In many cultures, grandfathers and grandmothers are revered and called “big father/big mother,” “big papa/big mama.” The addition of a new family member completes the basic intergenerational triangle of the family that includes grandparents, parents, and grandchildren (Van Ranst et al. 1995). Grandparents find a grandparenting role to be

generative, meaningful, productive, and full of satisfaction (Thiele and Whelan 2006), while communities and macro culture consider the role of grandparents to be multidimensional, dynamic, protective, and powerful.

Across cultures and centuries, the depth and breadth of grandparenting have been infinite. The role ranges from being an alloparent/care-giver, or a sibling, friend, teacher, therapist, mentor, a reservoir of the cultural traditions, and transmittals of cultural values and spirituality (Stelle et al. 2010). Custodial grandparenthood (aka skipped generation households) and residential grandparenthood are increasing rapidly. Custodial grandparenthood refers to grandparents that are legal guardians and are sole caregivers when biological parents are not present. Residential grandparenthood refers to grandparents who live with their children and grandchildren, are co-caregivers, but are not a legal guardian or sole provider.

Although it is debatable whether the increase in custodial and residential grandparenthood is a recent change, many cultures have always considered the role of grandparents an intrinsic part of the social fabric and natural way to preserve cultural values and heritage. Perhaps that is why, in Tongan communities, grandparents act as a bridge between ancestors and present and future generations and grandparents raise their grandchildren like their own (Ofahengaue Vakalahi et al. 2008). Similarly, in Asian cultures, *filial piety* and *respect for elders* sustain and strengthen the grandparents and grandchildren bond (Yee et al. 2008).

To further corroborate, in the USA alone, 7.3 million grandparents care for their grandchildren who are under the age of 18. Out of 7.3 million, 2.6 million grandparents are responsible for the basic needs of their grandchildren (US Census Bureau 2017). Likewise, in Europe, the grandparent's investment in their grandchildren is so extensive that Albertini (2016, p. 14 & 26) in his report on Survey of Health, Ageing, and Retirement (SHARE) suggested that grandparenting is "the most relevant downward flux of time resources." The amount of time that the respondents devote to this activity... seem to act as

substitutes of a weak public provision of formal childcare."

Notably, a remarkable increase in global life expectancy has added another layer to grandparenting. Globally, life expectancy has doubled since the 1800s. In the USA alone, the average life expectancy has increased from approx. From 60 to 80 years from 1950 to 2014 (Max Roser 2019).

In light of global improvements in life expectancy, the contributions of grandparents to an individual's development are not only protracted but also strengthened. Despite grandparenting being an intrinsic part of culture, in research, in the USA, little attention has been given to grandparents. Therefore, most of the studies included in this review are from European or Asian countries.

The entry will begin with a discussion of theoretical frameworks followed by the impact of grandparents on grandchildren' developmental outcomes, grandparenting role and grandparents, factors moderating grandparenting, and implications for social law and family policy and research and practice.

Theoretical Frameworks and Grandparenting

Allen et al. (2019) suggested the importance of integrating theoretical frameworks while researching grandparents. Applications of the theoretical frameworks describe and clarify the social mandates of role expectations and commitments to support each member of the dyad: in this case grandparent and grandchild. The authors also emphasized that grandparenting is a multidisciplinary area. Therefore holistic approach is necessary to appreciate the depth and breadth of the relationship thoroughly. For instance, grandparents as a social status can be a function of the family, community, and macro culture. How each of these interacts to provide dimensions and refinement to the grandparenting role and relationship needs to be further examined. To theorize, Allen et al. (2019) applied five theoretical frameworks. These theoretical frameworks are:

- (a) **Family Ecological Theory (Bronfenbrenner 1986, as cited in Allen et al. 2019).** The theory takes into account how various systems such as *micro*, *meso*, *exo*, *macro*, and *chrono* interact and strengthen the processes of grandparenting. As stated above, the increasing life expectancy and existing values related to *filial piety* may contribute to grandparents experiencing role enhancements (*chrono*). Conversely, the relationship may remain weak if the parents (*micro*) do not consent or approve of the relationship. Subsequently, the relationship between grandparents and their children along with other factors may dictate the frequency of contact and investment in grandchildren (Uhlenberg and Hammiii 1998).
- (b) **Family Systems Theory (Kerr and Bowen 1988, as cited in Allen et al. 2019).** The micro-level theory explains that families are a system and each member has a responsibility of sustaining the smooth functioning of the system to prevent disequilibrium. A loss or change in the life of one member, for example, the death of parents, reverberates throughout the system, and unless other members, in this case, grandparents, take over the role of custodial parents, the family system will remain in disequilibrium.
- (c) **Life Course Theory (Elder et al. 2003; as cited in Allen et al. 2019).** The life course theory focuses on the concept of linked lives across generations and suggests that changes in one generation will reverberate across generations impacting individual trajectories. To illustrate, *intergenerational solidarity* in many cultures mandates individuals to care and support each other. Thus, grandchildren's feeling of commitment toward their grandparents can be an act of reciprocity to repay for the care and support grandparents provided them in early or later years or could be an observational impact of watching their parents taking care of their parents (Even-Zohar and Sharlin 2009).
- (d) **Social Exchange Theory (as cited in Allen et al. 2019).** The theory takes into

consideration evaluation of interactions between individuals in a dyad. Thus, according to the theory, the members of the dyad in this case grandparents and grandchildren before becoming invested in their relationship carefully consider available resources, its associated costs to them, and how they would be benefitted. Imaginably, many grandparents may continue to be invested in their children as they see role satisfaction as a benefit (Allen and Henderson 2017).

- (e) **Family Stress and Resilience Theory (Hill 1958, as cited in Allen et al. 2019).** The theory, when applied to custodial grandparents or parents of low SES, offers a robust rationale behind the emergence of stress and mental health issues in grandparents as a result of increasing demands. The theory also brings into light the importance of social support in buffering the negative impacts of increasing demands on grandparents.
- (f) **Feminist Theory and Intersectionality (Allen and Henderson 2017).** Although an underutilized framework, Allen et al. (2019) suggested that the feminist theory accounts for grandmothers being more involved in caregiving and emotional labor than grandfathers. It also explains how the intersectionality of race, gender, SES, disabilities, and age may influence grandparenting.

Please note that other theories, such as kin selection theory and paternity uncertainty, are discussed in the section on factors moderating grandparenting.

Grandparents and Grandchild's Developmental Outcomes

It is a common knowledge that differences in extended family relations of an individual contribute to the differences in his/her developmental outcomes because of the alterations in the child-rearing environment. Among extended family members, grandparents contribute significantly to the development of their grandchildren and

remain prominent parental figures into adulthood (Mills et al. 2001). Even when grandchildren do not live with their grandparents, the indirect effects on the grandchild's development are significant. Perhaps that is why De-Guzman et al. (2018, p. 520) consider grandparenting and grandparents' role as a "vibrant influence and a synergistic force of endearing, endowing and enduring."

The direct and indirect effects of grandparenting on the developmental outcomes of an individual have been observed in all domains of development ranging from enhancements in interpersonal relationships to academic performance and physical activities.

In terms of physical and competitive activities, a study of Latino families reported that grandparents might provide direct support by taking grandchildren to sports camps, may advise on the positive impacts of physical activities, or offer tangible rewards to motivate grandchildren to participate in sports (Xie et al. 2017). The engagement in physical and competitive activities may further boost their grandchildren's sense of industry (Silverstein and Marengo 2001).

In the same vein, Møllegaard and Jaeger (2015) found that Danish grandparents' cultural capital (noneconomic resources such as knowledge, skills, and education) had a significant impact on grandchildren's academic performance and educational success. Likewise, Anderson et al. (2018) conducted a systematic review and reported that in 58% ($n = 69$) of the studies, grandparents' SES had a positive and significant effect on the grandchildren's educational outcomes regardless of the parents' SES.

Lastly, many researchers have reported that grandparents transmit positive attitudes and values, which may promote positive social-emotional development (Yusuf 2014). The positive emotional bond between grandparents and grandchildren is associated with improved prosocial behaviors, a stronger sense of self, development of healthy relationships and connections with peers, improved emotional regulation and resilience, and a decrease in aggressive behaviors (Kemp 2005; Sheridan et al. 2011; Hammer 2017; De Guzman et al. 2018).

Grandparenting Role and Grandparents

Overall, grandparents are essential agents of positive individual outcomes among the grandchildren. Having said that, grandchildren also play a crucial role in the development of physical, mental, and social outcomes of grandparents.

Kivnick (1982) proposed to shift the focus of research and emphasized grandparenting as a dyadic relationship rather than an individual experience. He then conducted a factor analysis of five factors related to grandparenting. These five factors were grandparents/grandparenting as (a) centrality to identity and meaning to life, (b) valued elder, (c) immortality through the clan, (d) reinvolvement with personal past, and (e) spoil/indulgence. The author validated the symbolic interaction theory and suggested that grandparenting offers ample opportunities to create meanings and identities for grandparents including enhancements in social status. Grandparenting is associated with positive health outcomes and well-being, closer relationships with grandchildren and children, higher levels of role satisfaction, perceptions of meaningful and productive life, and lower depressive symptoms among grandparents (Hayslip Jr. and Kaminski 2005; Choi and Zhang 2018).

Nevertheless, the grandparenting role comes at a cost and may have physical, psychological, and financial consequences on grandparents. Notably, the negative consequences are amplified among custodial grandparents of children with developmental disorders and mental illnesses in comparison with noncustodial and nonresidential grandparents. Given below are justifications for the unfavorable outcomes.

First, custodial grandparents have to shift their role from being a grandparent to a parent (Newman 2004) at an age and a developmental phase when parenting might not be conducive to their mental and physical health. Second, grandparents have reported to experience role ambiguity, higher levels of stress and anxiety, shame, guilt, conflict, anger, resentment, and financial drain because of adverse behaviors of not only grandchildren but also their children.

Finally, many grandparents after the loss of their children may worry about the well-being and future of their grandchildren (Minkler 2005; Waldrop and Weber 2001; Smith and Palmieri 2007).

Consequently, custodial grandparents may experience a decrease in the quality of social relationships and marital satisfaction (Minkler et al. 1992; Jendrek 1993) which may further result in poor mental and physical health of grandparents (Goodman et al. 2008).

Factors Moderating Grandparenting

Several factors may moderate grandparenting and their investment and involvement with grandchildren. Given below is a review of some of these factors.

Genetic relatedness and paternity uncertainty. Contributions of grandparents were measured in terms of unequal investment in their grandchildren. Although the definition of an investment may vary in research, it is often reported in terms of emotional closeness, degrees of contact, preferential treatment among grandchildren, and allocation of resources/or giving gifts.

At a theoretical level, the issue of unequal investment (aka discriminative care by paternal and maternal grandparents) is explained by paternity uncertainty, kin selection theory, and preferential investment hypothesis. Paternity uncertainty refers to perceptions of genetic relatedness; kin selection theory refers to the regulation of investment in kin, based on genetic relatedness; and the preferential investment hypothesis refers to preferential treatment in case of more certain kin. Studies that provide evidence for the positive associations between genetic relatedness and investment by grandparents are reviewed below.

Even though grandparents and grandchildren share 25% of their genes, maternal grandparents and paternal grandparents may invest differently. According to the paternity uncertainty and preferential investment hypothesis, maternal grandparents, especially the maternal

grandmother, are completely certain of the genetic relatedness. On the contrary, paternal grandparents, especially the paternal grandfather, are completely uncertain of the genetic relatedness.

The theoretical framework was tested and supported by researchers who applied preferential investment hypotheses to grandparenting. DeKay (1995) and Laham et al. (2005) concurred with the idea of unequal investment and discriminative care by paternal and maternal grandparents and suggested that maternal grandmothers invested the most, followed by maternal grandfather and paternal grandmother. The paternal grandfathers invested the least in their grandchildren. Unsurprisingly, maternal grandmothers and their grandchildren experienced a higher degree of emotional closeness and contact (Euler and Weitzel 1996; Bishop et al. 2009).

Furthermore, Tanskanen et al. (2014) added another layer to the issue of genetic relatedness and found that grandparents' involvement is higher for biological grandchildren than compared to step-grandchildren, thus providing another corroboration for the positive associations between genetic relatedness and investment in grandchildren.

Despite support in earlier studies, recently, researchers have criticized the emphasis on genetic relatedness and argued that the issue of discriminative care is complex and an agreement with the preferential investment hypothesis is questionable. Igel and Szydluk (2011) and Coall et al. (2014) suggested the integration of a comprehensive framework that includes sociological, economic, psychological, cultural, and political factors to examine grandparents investment.

Personal and Contextual Factors

In order to examine personal and contextual variables that influence grandparents' involvement in terms of frequency of contact, Uhlenberg and Hammiii (1998) categorized them into three main variables. These variables were a) opportunity variables that include geographical proximity, number of grandchildren sets, grandparents' health, and their employment status; b) gender/

family variables that include being a female, marital status of grandparents, and quality of relationship between parents and grandparents; and finally c) sociodemographic variables that include age, race, and educational status of grandparents.

In terms of opportunity variables, Uhlenberg and Hammiii (1998) reported that geographic proximity was the strongest predictor of frequency of contact, yet relationship with their children can mediate frequency of contact and quality of relationship. Thus, grandparents who live further away cannot be involved in day-to-day routines of their grandchildren consistently. Even when grandparents live closer to their grandchildren, their children and their relationship with them can influence the frequency and intensity of care provided. Thus, parents can act as gatekeepers of grandparents' involvement aka parent-as-mediators.

In terms of gender and family variables, first, the number of grandchildren or more sets of grandchildren may result in splitting time between sets and lower involvement or increased preference for a particular set of grandchildren. Second, unsurprisingly, grandmothers were found to be more actively involved than grandfathers and maternal grandmothers were more engaged in grandparenting than paternal grandmothers. Finally, married grandparents were more involved than widowed, remarried, and divorced. The findings on married and divorced/remarried grandparents may be the consequence of the negative ramifications of divorce on the relationship between parents and their children. Divorced and remarried grandparents either move farther away or get more involved with their new family (Uhlenberg and Hammiii 1998).

In terms of sociodemographic variables, advancing age resulted in lower physical competence to care and thereby resulting in infrequent contact and lower involvement. Interestingly, race and educational status did not significantly impact the frequency of contact (Uhlenberg and Hammiii 1998).

Recent research. Most findings of Uhlenberg and Hammiii (1998) have been replicated with similar findings. Silverstein and Marengo (2001) and King (2003) reported that divorced

grandparents and grandchildren share a weaker bond, are less involved in grandparenting, and contribute less frequently and intensely than married grandparents. The reasons for lower levels of involvement can be many such as grandparents live farther away or they may not have a good relationship with their children who serve as mediators between them and their grandchildren.

However, for custodial grandparents, Sands and Goldberg-Glen (2000) and Choi et al. (2016) contradicted the idea of advancing age and lower involvement. The researchers suggested that the younger (middle-aged), not older, grandparents invest less in their grandchildren. Lower involvement with grandchildren can be because middle-aged grandparents are still employed and therefore may often experience higher stress and anxiety due to competing demands between caregiving and professional commitments. Likewise, the cumulative negative impacts of role conflict, competing demands, and developmental disorders in grandchildren are higher in middle-aged grandparents than older grandparents.

Meanwhile, Mhaka-Mutepfa et al. (2015) suggested that in Zimbabwe, grandparents of higher SES, personal competence in terms of self-esteem and self-efficacy, resilience, and social networks experienced more resilient grandparenting than those who did not have these characteristics. Notably, in this study, advancing age was again associated with decreased caregiving competence and lower involvement.

Conclusions and Implications

Based on the evidence stated above, we can conclude that universally, a significant number of grandparents are involved and invested in grandparenting. Grandparenting provides potential benefits to grandchildren in all domains of their development and buffers the effects of childhood adversity, but the role comes at a cost to grandparents in terms of increased stress, depression, and financial drain. Besides, custodial grandparents may be left to cope with trauma, loss, and legal and medical repercussions of their

dysfunctional children. Interestingly, in the presence of adequate social support, the adverse outcomes may diminish and grandparents may feel more resilient in their role (Mhaka-Mutepefa et al. 2015).

The above findings have important implications for family policy and intervention programs. Similar to any caregivers, grandparents, especially custodial grandparents, require social support to sustain and effectively navigate their role (Kresaka and Gallagher 2014). Parent training programs, case management services, and federal policies and programs such as respite care, financial assistance, SSI, health insurance, and more can benefit grandparents tremendously. Sparng et al. (2015) further argue that custodial grandparents' interventions must integrate a trauma-informed approach to help them cope with grief and loss of their grandchildren, whereas Choi et al. (2016) advocated customized individual interventions to support the dyadic relationship and mitigate the effects of negative outcomes.

Definition

Relationships between grandparents and grandchildren are a part of intergenerational family relations. According to sex and lineage, there are four possible types of biological grandparents: maternal grandmother, maternal grandfather, paternal grandmother, and paternal grandfather. Moreover, there are several possible nonbiological grandparent–grandchild dyads that are not the topic of this chapter. Interaction between grandparents and grandchildren is typically not only between those two generations but involves the middle generation that is the parents of (grand)children. Especially when grandchildren are small, the parents may act as gatekeepers between grandparents and grandchildren, and, thus, the quality of parent–grandparent relationship is important for the quality of grandparent–grandchild relationship. In evolutionary literature, the grandparent–grandchild relationship is typically studied from the viewpoint of grandparents' fitness interests, and it often encompasses biased grandparental investments and the child outcomes of grandparental presence and investments.

Introduction

Recent rise in life expectancy have increased shared years of life between grandparents and grandchildren. At the same time, the number of (grand)children has decreased in Western world. This means that the time grandparents spent with each grandchild may increase (Coall and Hertwig 2010). Due to these recent demographic transitions, the relationship between grandparents and grandchildren has nowadays the potential to be more important than ever before.

In evolutionary literature, humans are often defined as a cooperative breeding species (Hrdy 2009; Sear 2015). Cooperative breeding means that human's species-typical child-rearing involves, in addition to the child's biological mother, other caretakers (so-called allomothers) who are needed because of humans' exceptionally long dependent childhood. These allomothers may include, for instance, the child's father, older siblings, aunts, uncles, and grandparents.

Hamilton's (1964) kin selection theory explains why it is beneficial for kin members, such as grandparents, to help their close kin, especially in the descending line. Kin selection theory states that an individual can enhance its inclusive fitness by supporting close relative's reproductive success (indirect fitness), at the expense of its own direct fitness (Hamilton 1964). According to kin selection theory, all else being equal, people should favor and invest more in their close kin than more distant kin or non-related friends. In addition, Trivers' (1972) theory of parental investment, which easily extends to the theory of grandparental investment, accounts all investments (grand)parents make in their offspring. In the case of grandparents, these investments include, for instance, contact frequencies, childcare help, emotional support, and financial assistance (Euler 2011).

In the case of grandparenthood, there are several ways one can have nonbiological grandchildren which makes the study of nonbiological grandparenthood very complex. Moreover, all nonbiological (grand)children are not necessarily treated the same way. Adopted children (and their children) may be more desired than

stepchildren, and thus the investment made in adopted children (and their children) may not differ from the investment made in biological children and their offspring (Segal et al. 2015) although there is evidence that grandparents in general invest more in their biological than non-biological grandchildren (Coall et al. 2014). In this article, the relationship between grandparents and grandchildren is reviewed from the viewpoint of biological grandparenthood.

The relationship between grandparents and grandchildren is almost inevitably influenced by the middle generation (i.e., the parents), at least when the grandchildren are young, because grandparental support may be channeled to the grandchild indirectly via grandparents' own children or their children's spouses instead of a direct support (Euler 2011). Parents can guard access to a grandchild and act as gatekeepers between grandparent and grandchild. This chapter considers different aspects of the relationship between grandparents and grandchildren by concentrating on biased grandparental investment pattern, parents' role as gatekeepers, and grandparents' positive and negative impact on grandchild well-being.

Biased Grandparental Investment Pattern

All grandparents have on average a 25 % chance of having the same genes with their grandchildren, and, thus, according to the kin selection theory, they should invest equal amount in their grandchildren. However, empirically, this is not the case. One of the most robust finding in grandparent studies is that typically maternal grandmother invests the most in grandchildren, following maternal grandfather and paternal grandmother who either invest equally or maternal grandfather invests slightly more, and finally paternal grandfather who invests the least (Coall and Hertwig 2010; Euler 2011). Reason for this biased grandparental investment pattern stems from human's sex-specific reproductive strategies, paternity uncertainty, and a tendency to invest preferentially in more certain kin.

Sex-specific reproductive strategies predict that due to more obligatory maternal than paternal investment, grandparents should allocate their support more probably in their daughter and her children than their son and his children (Euler 2011). Paternity uncertainty in turn assumes differences in the investments according to the certainty of the genetic relatedness. Paternity is more uncertain than maternity, and this creates the pattern where maternal grandmother has no uncertainty that the grandchild is hers, maternal grandfather and paternal grandmother both have one link of uncertainty, and finally paternal grandfather has two uncertain links (Euler 2011).

Paternity uncertainty does not directly explain the commonly found difference between maternal grandfather and paternal grandmother. Maternal grandfathers typically tend to invest more in their grandchildren than paternal grandmothers do, although the genetic certainty is the same. The result is sometimes explained by incidental exposure, meaning that maternal grandfathers' larger amount of investment is due to their spouse, the maternal grandmother, who invests the most (Pollet et al. 2006), but it can also be due to the fact that paternal grandmothers have additional grandchildren via daughter(s) and thus they may prefer to invest in their daughter's (who are more certain kin) than their son's children (Laham et al. 2005). Preferential investment in more certain kin hypothesis has gained support in a large study of European grandparents (Danielsbacka et al. 2011).

Other factors, besides the sex and lineage of a grandparent, are also associated with grandparental investments. These are quality of relationship between grandparent and parent, geographic distance, number of grandchild sets, and marital status of grandparent (Uhlenberg and Hammill 1998). Also grandparent's age and health as well as grandchild's age may matter, because older grandparents who are in poorer health may not be able to have so intense relations with grandchildren as younger and those who are in better health (Danielsbacka and Tanskanen 2012). Also the younger the grandchildren are, the more frequent the contacts with grandparents usually are. In the case of the sex of a grandchild, the

results are mixed. Theoretically, the asymmetric impact of X- and Y-chromosome inheritance could affect the bias in grandparental investment (Euler 2011), because in respect to sex chromosomes the grandchildren are asymmetrically related to their maternal and paternal grandparents. Studies concerning the asymmetric impact of X- and Y-chromosome inheritance have, however, produced mixed results, and no consistent association between grandparental investment and grandchild sex has been found (e.g., Chrastil et al. 2006; Tanskanen et al. 2011).

The above described pattern of biased grandparental investment is remarkably solid in contemporary Western societies even when other potentially confounding factors are controlled for (e.g., Danielsbacka et al. 2011). However, strong patrilocal or patrilineal preference, which was common in previous societies and is in some contemporary societies (e.g., in contemporary China), may override the effects of sex-specific reproductive strategies and paternity uncertainty (Kaptijn et al. 2013; Lahdenperä et al. 2004; Pashos 2000). The reason for this is that in patrilocal societies, the emotional options for attachment to maternal kin do not get an opportunity to develop and at the same time fathers' certainty of their fatherhood is usually enhanced.

Parents as Gatekeepers

If the relationship between grandparents and grandchildren is looked only from grandparents' viewpoint, it is often forgotten that grandparents cannot take for granted that their investment is accepted. Because the relationship and interaction between grandparent and grandchild can be direct or indirect the middle generation (parents) have an important mediating role. The mediating or gatekeeping role of parents is more significant the younger the grandchild is. It is shown in many studies that the quality of the relationship between parental and grandparental generations is associated with the quality of grandparent–grandchild relationship (e.g., Michalski and Shackelford 2005).

In addition, it is often ignored that the relationship between grandparents, parents, and grandchildren includes also in-laws, who are genetically non-related to each other. As an extension to kin selection theory, Hughes (1988) has argued that in-laws, who are usually not closely genetically related, become “inversely” genetically related to each other through common descendants. Thus, in terms of parent–grandparent relationship, the in-law relationship might be more influenced by the advent of a (grand)child than biological parent–grandparent relationship, and the quality of in-law relationship may also be more important for the good grandparent–grandchild relationship than the relationship between grandparent and his or her own child (Danielsbacka et al. 2015).

From evolutionary viewpoint, due to consanguinity, sex-specific reproductive strategies, and paternity uncertainty, the quality of the relationship between eight different parent–grandparent dyads should be expected to be better between genetic kin and among them the best between maternal grandmother and her daughter and worse between in-laws and among them the worst between paternal grandfather and his daughter-in-law, although in empirical studies the worst relationship seems to be between paternal grandmother and her daughter-in-law (Euler et al. 2001). Thus, based on relationship quality between parent and grandparent generations, the gatekeeping role of a daughter-in-law toward paternal grandparents should be the most significant.

The Outcomes of Grandparental Presence and Grandparental Investment

In evolutionary research, it has been a great subject of interest whether grandparents can improve (or could have improved) their inclusive fitness by investing in their children and grandchildren. In studies analyzing the historical and traditional societies, the child outcomes of grandparental presence have been often measured by fertility and child survival. In modern societies, however, grandparents are not anymore needed to keep the

children alive as they were in subsistence societies, and, thus, the outcomes of grandparental investments should be measured with milder indicators of child well-being (Coall and Hertwig 2010).

In high fertility and high child mortality societies, the presence of grandparents has been found to improve grandchild survival (e.g., Sear and Mace 2008), and grandparental presence may have also had influence on parent's age at first birth and the number of children (e.g., Lahdenperä et al. 2004). Also, nowadays grandparents may have an impact on parents' childbearing decisions (e.g., Tanskanen et al. 2014), and they may increase the grandchild well-being measured by, e.g., child development, educational success, and lack of emotional and behavioral problems (e.g., Tanskanen and Danielsbacka 2012). In addition, studies from contemporary societies also implicate that active grandparenting (i.e., caring and spending time with grandchildren) may improve grandparents' own health and well-being as long as caring duties are not overwhelming (Coall and Hertwig 2010).

Grandparental presence is not, however, always beneficial for grandchildren. Local resource competition model takes into account the possible detrimental effect of three-generational household units for the grandchild well-being (Strassmann and Garrard 2011). If local resources are scarce and/or grandparents are very old and in poor health, they may compete with grandchildren over limited resources and parental care and time. Previously, the local resource competition has been studied only in historical and contemporary subsistence societies (e.g., Strassmann 2011). However, resource competition may also explain the results gained in prior studies concerning contemporary societies that have found that child well-being is lower when children are living in three-generational households compared to two-generational families (e.g., Krueger et al. 2015).

Previously found detrimental effects of grandparental presence can also be due to the different fitness interests of different grandparent types which are based on sex-specific reproductive

strategies. For instance, the presence of mothers-in-law has found to have detrimental effects on child survival and well-being in traditional and historical societies (e.g., Leonetti et al. 2007; Volland and Beise 2005).

Conclusion

The relationship between grandparents and grandchildren is a part of an extended family relations which stem from the human's species-typical cooperative breeding system. In evolutionary literature, grandparent–grandchild relationship is often studied as a manifestation of grandparental investment and interest that have focused on its unequal distribution. Sex and lineage are one of the main determinants of grandparental investment, meaning that in contemporary Western societies maternal grandmothers are typically the ones who invest the most in grandchildren, following maternal grandfathers, paternal grandmothers, and finally paternal grandfathers. The pattern tends to remain robust even after several potential confounding variables are controlled for.

The relationship between grandparent and grandchildren is inevitably influenced by the middle generation. That is why the quality of grandparent–grandchild relations are often in some degree contingent upon the quality of parent–grandparent relations. Parents are in important position between the grandparents and grandchildren because they may either act as gatekeepers or enhance the interaction between grandparents and grandchildren. Parent–grandparent couples form eight dyadic relationships, each which quality can be predicted by sex-specific reproductive strategies and paternity uncertainty. In general, in-law relations are predicted to be worse than the relations between genetic kin. In-law relations may also be more easily influenced by the advent of (grand)children.

In evolutionary studies, the positive outcomes of grandparental presence and grandparental investments have been studied far more than possible negative outcomes of them. It has been

found that in previous societies as well as in contemporary traditional societies grandparental presence has associated with grandchild survival and the number of grandchildren born. However, it has also been found out that when there is a lack of resources, grandparents may compete with grandchildren over the local and family resources, and, thus, in some circumstances, the presence of a grandparent may have detrimental effects for child well-being. In addition, due to different fitness interests and reproductive strategies between grandparent types, the presence of mothers-in-law, in particular, may have detrimental effects for grandchild well-being. These potential harmful effects have not been studied in contemporary societies. In modern societies, the positive outcomes of grandparental investment have been confirmed in several studies.

Introduction

As early hominins developed into eventual *Homo sapiens*, a major step in their change in biological structure and the formation of bipedal locomotion was their change in environment. These early hominins transitioned from living in trees as modern primates do to moving down to savannahs and, as a result, changing their physiological structure through the gradual process of evolution to adapt to hunting and surviving on the African savannah. The savannah, or grasslands, provided a major change from hominins’ previous environment, including climate, elevation, and prey, among various other differences that worked in congruence to illicit change in these hominins – among those changes being bipedal locomotion.

Why Did We Leave the Treetops?

The exact reason as to why we left the treetops is a subject of debate within the evolutionary science community. A common question to evolutionary science is, “Well, if we’re human as a result of evolution, then why are there still monkeys today?” The answer to this question lies within this exact concept – that we left the trees some 5 million years ago to the ground, where we eventually moved out into savannahs. This departure then allowed that group of hominins to evolve differently over the course of millions of years, resulting in the changes that we see in our own bodies today, as compared to the physiological mechanisms still apparent in modern chimps. Some theorize that we didn’t simply go straight from the trees to the savannah – in fact, we may have spent a considerable amount of time living on the grounds of these forests rather than in the trees. This is supported by evidence such as remains of forest animals found nearby early

hominin skeletons – suggestive of hunting these animals on the ground floor of the forest. Modern chimps and gorillas spend a considerable amount of time on the floor; therefore a possible reason for our migration may simply have been our ancestors spending more time on the ground as compared to other apes and, as a result, adapting accordingly. Once enough adaptation was sufficient, our ancestors may then have moved on to other areas that were more suitable for their changes, given their loss of climbing ability and their increased ability to throw and create weapons due to their development of bipedal locomotion (Wheeler 1984).

Climate Change

Others theorize that our moving out into the savannah may have been a result of climate change (Demenocal 2004). Changes in seasonal patterns or climate may have resulted in changes to the forestation of these areas, as well as the kind of vegetation and prey that was available for our ancestors to survive. Certainly a depletion of these resources would have been a logical reason for our ancestors to move out and look for more suitable conditions outside of the forest and into the savannah where the climate change effects would have been less pronounced due to the dearth of trees in the area.

Were We “Pushed Out”?

Another theory is that our relatives such as early chimpanzees simply were more adept at climbing and therefore were in heavy competition for resources and space in the trees (Jacobs 2004). If they became more adept as a result of evolution and began to take all of the resources, it is possible that our early hominins simply migrated further down the trees and began to adapt to a new lifestyle whereby they could hunt for resources by not competing with chimpanzees. Being pushed down to our new environment would have required significant changes in our biological structure, which may have also been a reason for the development of bipedal locomotion.

Conclusion

Early hominins were forced to move into grasslands due to leaving the trees, whereby we developed the ability to walk on two legs in order to accommodate to our new environment and lifestyle. Although the reason why we left the trees is unknown, there are a number of theories that attempt to explain why we felt the need to move out of the trees. Among them are simply spending more time on the ground as many modern chimps and gorillas do, and therefore developing physiologically accordingly, and then moving out into savannahs with more resources. Another could have been climate change, whereby a lack of trees and resources forced us to move lower in elevation and eventually into grasslands to ensure survival. Lastly, it may also have been attributed to a competition in resources with our ancestors and simply pursuing areas where we could lessen competition and still benefit from gaining the resources found at the forest floor. Whatever it may be, it is undeniable that the change from moving out of trees and into flatland savannahs was a major contributing factor to human development through bipedal locomotion.

Definition

Gratitude, sympathy, and certain forms of empathy often result in behavior that benefits others at cost to the self. Making sense of these emotional phenomena from an evolutionary perspective is challenging, given they would seem to be non-adaptive for the individual. However, evolutionary processes such as kin selection, reciprocal altruism, and exaptation may give rise to mechanisms for these phenomena when immediate cost to the individual can translate into long-term survival or reproductive benefit. It is essential to clearly identify the nature of the phenomena under examination when evaluating or empirically testing evolutionary explanations for phenomena related to gratitude, sympathy, and, especially, empathy.

Introduction

Gratitude, sympathy, and empathy are challenging phenomena to understand from an evolutionary perspective. Most emotions can be readily conceptualized as evolutionary adaptations that have promoted individual survival and reproductive fitness. However, the terms *gratitude*, *sympathy*, and *empathy* refer to phenomena that may place a burden on the individual in terms of survival or reproductive fitness. Indeed, the phenomena identified by these terms can generate

prosocial behavior that increases the wellbeing of others, often at a cost to the self. Yet, it is possible to understand these phenomena from an evolutionary perspective if one considers how short-term cost to the individual can contribute to the longer-term fitness of individuals or to those genetically similar to them. But before undertaking such an analysis, first one must clearly establish the phenomena to which the terms gratitude, sympathy, and empathy refer.

Gratitude

Gratitude refers to a positive emotion evoked by perception that one has received benefit from the generosity of another (McCullough et al. 2001). The intensity of gratitude is affected by a number of perceptions of the benefactor. People report feeling more gratitude in response to a benefactor who they believe has (a) intentionally sought to benefit them; (b) is more relationally distant; and (c) has provided a benefit that is of high cost or high value. When people experience gratitude in response to a benefactor, research suggests that they are more likely to benefit their benefactor in return. Moreover, research suggests that expressions of gratitude spur benefactors to benefit others in the future (McCullough et al. 2001, 2008).

Sympathy

The term *sympathy* has been used to label two related, but distinct, emotional phenomena. The term was originally used to describe feeling the same emotional or affective experience as another person. However, the term is used by some contemporary social scientists to describe a feeling of concern for another in need. Still other social scientists label this emotional reaction *empathic concern* or *empathy* instead of sympathy (Batson 2011). Indeed, inconsistency in the use of the terms sympathy and empathy to describe related, but distinct, affective phenomena has been a source of much confusion in the literature. Sympathy (empathic concern) is produced by adopting the perspective of another in need. It is more

readily elicited by those who are considered not responsible for their own need, those whose welfare is valued, and those who are perceived as vulnerable or exhibit attributes associated with vulnerability (e.g., childlike characteristics; Batson 2009).

Experimental research suggests that the experience of sympathy (empathic concern) produces altruistic motivation. This mechanism is the focus of the empathy-altruism hypothesis (Batson 2011). Specifically, according to this hypothesis, sympathy produces altruistic motivation to increase the welfare of another as an end itself, rather than motivation to benefit the self. In turn, this motivation can lead to prosocial behavior that is costly to the self. Experimental studies have offered support for this intriguing hypothesis. Yet, these findings have long perplexed those seeking an evolutionary account of human altruism, especially because the vast majority of research consistent with the empathy-altruism hypothesis has involved the effects of sympathy on helping of genetically unrelated strangers (Batson 2011).

Empathy

The term *empathy* was first used by Titchener to describe the process of *emfühlung*, whereby an observer seeks to mentally project the self into the state of another person or object. However, the term empathy is now used to describe at least eight related, but distinct cognitive, affective, and behavioral phenomena. These phenomena include (a) *aesthetic perspective taking* (i.e., *emfühlung*); (b) *imagine-other perspective taking*, whereby one seeks to imagine the mental states of another; (c) *imagine-self-perspective taking*, whereby one seeks to imagine how he or she would think and feel in another's situation; (d) *accuracy in identifying the mental states* of others; (e) *feeling the same emotion or affective experience as another* in response to his or her situation or behavior; (f) *feeling other-oriented concern* (i.e., sympathy, empathic concern) for another in need; (g) *feeling self-oriented distress* in response to another in need; and (h) *adopting the same behavioral postures, expressions, or mannerisms* of another (Batson 2009).

Given the number of phenomena identified by the term empathy, it is unclear whether one can satisfactorily integrate all these concepts or even a subset of these concepts into a single undifferentiated theoretical construct. Also important to note is that it may be inappropriate to consider sympathy as distinct from empathy. Instead, it may be best to consider sympathy as one of many phenomena falling under the umbrella term *empathy*.

Unlike gratitude and sympathy, which appear related to prosocial behavior that benefits others at some cost to the self, a number of phenomena related to empathy are not necessarily prosocial. For example, perspective taking can generate sympathy or other forms of affective empathy that produce prosocial behavior that is costly to the self in some situations (Eisenberg et al. 2010). However, in other situations perspective taking can promote behavior that directly benefits the self, such as ability to more effectively interact with, learn from, and detect deceit in others (Tomasello 1999). In these situations, perspective taking can lead to attainment of positive outcomes or avoidance of negative outcomes that would directly increase one's relative fitness. Certain affective empathy phenomena (besides sympathy) may convey direct self-benefit as well. For example, a tendency to experience emotions similar to those of others in response to witnessing their reactions to situations may promote simulation of mental states that helps guide behavior and understanding of the environment (Decety and Grèzes 2006). Another empathy phenomenon, self-oriented distress caused by witnessing another in need, can lead to costly helping behavior, but this is not the preferred option. Instead, distress tends to evoke an egoistic motive to escape from the need situation (Batson 2011). Thus, it is not clear that all empathy phenomena produce behavior that benefits others at a cost to the self in all situations.

Evolutionary Explanations

Traditionally, evolutionary explanations for prosocial behaviors produced by gratitude and sympathy, and to a lesser extent some empathy

phenomena, involve a consideration of how they are linked to adaptations that promote one's own fitness, or one's inclusive fitness (the fitness of other individuals who share genes similar to the self), despite incurring immediate cost to the self. Evolutionary processes that can speak to the emergence of such adaptations include reciprocal altruism (Trivers 1971), kin selection (Hamilton 1963), and exaptation (Buss et al. 1998).

Gratitude. As noted above, gratitude appears to motivate helping of benefactors directly or to motivate expression of gratitude to benefactors. Gratitude expression then reinforces benefactors to benefit others in the future. Given that this exchange process seems most potent among relationally distant individuals, who are more likely to be nonkin, the emergence of mechanisms that give rise to gratitude and the reinforcement of receiving gratitude expressions suggest adaptations resulting from reciprocal altruism (McCullough et al. 2008). Specifically, gratitude adaptations may have emerged because interactions between individuals who possessed traits for feeling and expressing gratitude and individuals who possessed traits for sensitivity to gratitude expressions produced greater relative reproductive advantage overtime than did interactions between individuals who did not possess such traits.

Sympathy. Upon casual consideration, the psychological mechanism of sympathy (empathic concern) and the altruistic motivation it evokes can be explained by kin selection. That is, those with traits for sympathy were more likely to benefit and promote the fitness of those with similar genes. The tendency for people to experience more sympathy for those in need whose welfare they value seems consistent with this explanation. However, the kin selection explanation cannot account for empirical evidence of sympathy-induced altruism from experimental studies of helping directed toward strangers (Batson 2011). In many of these experiments, there is no anticipation of interaction and no genetic similarity between benefactors and those they benefit.

One possibility is that the capacity for sympathy is an adaptation evolved to promote care of

offspring or young (as a result of kin selection) that can combine with capacities for complex cognitive representation and abstraction that arise from adaptations selected to promote fitness in behavioral domains unrelated to care of offspring. This combination of capacities may permit generalization of sympathy to situationally vulnerable non-offspring (c.f., Batson 2011). Thus, sympathy-induced altruism toward strangers could be a more complex psychological mechanism upon which natural selection did not operate. However, this expansion of parental nurturance to nonkin may well involve the interplay of two mechanisms upon which natural selection did operate for different functional reasons.

Empathy. As discussed previously, the direct benefit to the individual's fitness in cases where the phenomena clearly promote self-benefit (e.g., detection of others' intent to deceive via perspective taking) can readily explain a number of empathy-related phenomena. In cases where empathy phenomena appear to promote benefit of others at cost to the individual, understanding of the phenomena from an evolutionary perspective can be quite challenging. One can seek to identify adaptive functions of such phenomena that may have emerged as a result of either kin selection or reciprocal altruism. Alternatively, some empathy phenomena may be better explained not as adaptations but rather (a) as exaptations, which are earlier adaptations co-opted through the process of natural selection to address a new fitness-promoting function, (b) as spandrels, which are by-products of earlier adaptations co-opted through the process of natural selection to address a new fitness-promoting function, or (c) as by-products of previous adaptations that serve no fitness-promoting function (c.f., Buss et al. 1998).

Conclusion

Gratitude, sympathy, and certain forms of empathy promote behavior that benefits others at cost to the self. Understanding the evolutionary origins of the mechanisms that give rise to these phenomena poses challenges, given that such mechanisms are

not obviously adaptive. However, evolutionary processes such as reciprocal altruism, kin selection, exaptation, and spandrels may account for these mechanisms when immediate cost to the individual can translate into long-term survival or reproductive benefit under certain selection pressures. It is essential to clearly identify the nature of the phenomena under examination when evaluating or empirically testing evolutionary explanations for gratitude, sympathy, and especially the variety of empathy phenomena.

[The gravity hypothesis of sexual size dimorphism](#)

Definition

A hypothesis explaining why extreme sexual size dimorphism (SSD), with males being hundreds of times smaller than females, may have evolved (Moya-Laraño et al. 2002). This hypothesis proposes that the race to reach sexually receptive females favors smaller males, particularly in those large species in which females live high up in tall vegetation. The underlying mechanism invokes the Earth's gravitational pull: all else being equal, small males can climb faster than large ones to reach females. Some recent updates and refinements of the hypothesis, including other traveling modes, may actually have stronger explanatory power (Moya-Laraño et al. 2009; Corcobado et al. 2010).

Introduction

In most animal species, males and females differ in many aspects of their morphology, physiology, and behavior, well beyond their fundamental differences in reproductive biology (Fairbairn et al. 2007). Why these differences exist has been a key question biologists try to answer since Darwin (1871). Body size is the most

important characteristic of any individual because body size is intimately related to all other aspects of life, such as physical strength, metabolic rate and thus energy and nutrient requirements, and egg production. Body size is also the trait for which differences between males and females are most common across animal species (Fairbairn et al. 2007). Key questions are: Why do males and females differ in size? Why is there large variation with respect to the degree of these size differences? and When and why are these differences extreme?

Several hypotheses try to explain the evolution of extreme sexual size dimorphism (SSD) in the group of terrestrial animals in which this phenomenon is common, the spiders (Araneae). Indeed, in some spider species, females may be one hundred times heavier than males (Foellmer and Moya-Laraño 2007). The hypotheses put forward so far to explain this phenomenon have been reviewed somewhere else (Foellmer and Moya-Laraño 2007; Moya-Laraño et al. 2013). In brief, the sexual cannibalism hypothesis was initially put forward by Darwin (1871) and states that males evolved much smaller body sizes than females because they would be disregarded by females as potential prey (i.e., too small to be profitable) or because they would be able to enter the female's web without being detected by her in the first place, prior to the onset of copulation. Evidence supporting this hypothesis (e.g., larger males being more likely killed by females) is scant (Foellmer and Fairbairn 2004; Moya-Laraño et al. 2013). On the contrary, recent evidence suggests that extreme SSD (i.e., large female size relative to male size) in spiders evolved first and that sexual cannibalism evolved subsequently in dimorphic species, presumably because females were large enough to catch males without putting themselves at risk (Wilder and Rypstra 2008). In addition, in nonweb building species with moderate SSD females actually prefer to kill smaller, not larger males (Prenter et al. 2006). Another hypothesis, the differential mortality model (DMM), explains the evolution of extreme SSD by selection favoring earlier male maturation at a small size, as large male body size for fighting for access to females is not favored when male mortality is increased relatively to that

of females, due to the fact that males are the sex traveling in search of females. This difference should be therefore more pronounced in species which are sit-and-wait predators compared to actively hunting spiders, as in the latter both sexes move around (Vollrath and Parker 1992). Thus far this hypothesis has only been partially supported and only when real estimates on differences in mobility/mortality between the sexes were used (De Mas et al. 2009). One of the most accepted hypotheses explaining the evolution of SSD in spiders is the fecundity selection hypothesis (FSH) which states that a history of selection favoring fecundity (egg number) has led to the evolution of large body size in females, because in ectothermic animals larger females lay more eggs (Head 1995; Prenter et al. 1999). The evolution of extreme SSD would then be explained by gigantism evolving much faster in females than in males. All of the above hypotheses explain the evolution of SSD by focusing on selection acting on one or another sex. However, none of them can successfully explain the entire range of SSD observed across spiders (Foellmer and Moya-Laraño 2007). For instance, why do some species with very large (giant) females have dwarf males while others have males that are similar in size to females?

The gravity hypothesis (GH – Moya-Laraño et al. 2002) addresses this shortcoming. The GH explains the evolution of extreme SSD as the result of selection acting upon males, favoring those individuals that are more successful at reaching females when these are receptive (sexual selection as a result of scramble competition – Ghiselin 1974). The basic tenet of the GH is that there are marked differences in microhabitat occupancy across different spider taxa, with some spider taxa living on the ground, while others inhabit microhabitat patches on trees, in tall habitats. Therefore, from the point of view of a male that is searching for receptive females, the habitat may show strong verticality; one that needs to be overcome in order for the male to be able to find mates.

A simple biomechanical model (Moya-Laraño et al. 2002) showed that for a male to reach a female that lives in tall vegetation, being smaller is favored, as the speed at which a smaller male

could climb would be higher, thereby facilitating successful encounters with receptive females. Using the comparative method in evolutionary biology, the authors tested two main predictions of the GH: (1) with increasing height of the habitat females live in, SSD increases (i.e., male size relative to female size decreases) and (2) this effect is stronger for larger spider species, as in those the negative effect of gravity should be more pronounced. Both predictions were met by the analysis of Moya-Laraño et al. (2002). However, further research, along with misunderstandings of some of the tenets of the GH, fueled a fruitful controversy in the years following its publication.

More Recent Variations and Improvements of the GH

The Curvilinear GH

Moya-Laraño et al. (2009) published an update of the GH (see also Foellmer and Moya-Laraño 2007). By running spiders on vertical inclines and reanalyzing the data in Moya-Laraño et al. (2002), they showed that (1) there is not a simple negative relationship between climbing and speed, but a curvilinear one with an optimal body size for climbing, and (2) superimposing this relationship on the patterns of SSD across spider species, species in tall habitats showed a clear top threshold on male size which explained a non-linear male (Y) female (X) relationship, which was not predicted (and in fact did not occur) in spiders inhabiting close to the ground. A post hoc model was also built (Moya-Laraño et al. 2009) which explained why we should expect a parabolic climbing speed pattern with body size in spiders. Although this hypothesis further contributed to explain the patterns of extreme SSD across spider species, there was still an unexplained part of the pattern, caused by those gigantic spider taxa that inhabit tall habitats but in which SSD is moderate. The bridging GH solves this puzzle.

The Bridging GH

This hypothesis (Corcobado et al. 2010) considers an additional (and largely neglected) travel mechanism of spider males, moving along a silk thread, or bridging (Moya-Laraño et al. 2007b). During

bridging the spider hangs from a silk thread and releases silk that is carried away by the wind until it finds an anchor point (e.g., a plant) on the opposite end (i.e., in the direction of the wind). Once the silk has been anchored the spider tenses the thread and starts walking upside-down to reach the other end. A biomechanical model (Rodríguez-Gironés et al. 2010) showed how heavier spiders are limited in the use of this mechanism for traveling, especially at longer distances, because the silk released from the minor ampullate silk glands (one of the glands producing silk in spiders) elongates more strongly in the ground direction with a heavier load, ending with the spider on the ground, thus making this dispersal mechanism not efficient. A good solution to travel efficiently using this mechanism is thus also to be small. This hypothesis was tested by inducing spiders to bridge under laminar wind flow (Corcobado et al. 2010). The authors found that (1) both large males and females were less prone to bridge relatively to smaller spiders and (2) the degree of sexual dimorphism in bridging propensity was negatively correlated with the degree of SSD. In a direct test, Morse (2014) found that male size is positively related to bridging speed in the crab spider *Misumena vatia*, as predicted for this species which has small males of a mean size of only 4 mg (well below the bridging threshold of 118 mg predicted by the bridging GH). Females, on the other hand, are up to two orders of magnitude heavier. This hypothesis is the most integrative to date, as it also explains the exceptions; i.e., those spider taxa in which the female is gigantic and inhabits tall places but in which SSD is nonetheless moderate. These correspond to spider groups in which traveling in search for mates is not done by bridging, as for instance the families Ctenidae or Sparassidae.

Findings and Controversy

A complete understanding of the evolutionary processes underlying current trait distributions, such as the different body sizes of males and females, requires investigating the evolutionary history of the traits within a taxon and the factors which currently favor and maintain trait

distributions in populations (Foellmer and Moya-Laraño 2007). Theoretical models, such as the GH and its refinements, make informed predictions for both the evolution and the current maintenance of traits, as these models establish a maximum body size for males. The long-term evolution of characters is best addressed in comparative analyses which are corrected for phylogenetic relationships. To test whether gravitational effects are driving current selection processes in populations, field studies estimating male fitness during mate search as a function of morphology and lab experiments involving locomotion trials are necessary (Foellmer et al. 2011; Moya-Laraño et al. 2013). Importantly, selection processes favoring current body size distributions in males and females do not need to be the same as those that initially led to the evolution of sexual size dimorphism.

All comparative analyses to date find evidence for an important role of gravity in the evolution of SSD, and extreme SSD in particular in spiders, and thus support the GH and its refinements (see above). The predictions of the GH with regards to body sizes favored by selection during mate search and during locomotion trials depend on the male size distribution under investigation, the predominant mode of locomotion (running or bridging), and the habitat context. In many species with extreme SSD, mean male size is well below the threshold for optimal climbing speed predicted by the curvilinear GH (7.6 mm body length or 43 mg body mass) and even the largest males do not reach this threshold (Cheng and Kuntner 2014; Hormiga et al. 2000). For such species, the predicted large male advantage during mate search in the field was found for the orb-web spider *Argiope aurantia* (Foellmer and Fairbairn 2005) and the crab spider *Misumena vatia* (Morse 2014) and in running trials on vertical structures in the laboratory in *Argiope aurantia* (Foellmer et al. 2011). No effect of male body size during mate search was detected in the widow spider *Latrodectus hasselti* (Andrade 2003), the orb weaver *Nephila plumipes* (Kasumovic et al. 2007), and for *Latrodectus hesperus* (Brandt and Andrade 2007), *Argiope keyserlingi*,

and *Nephila plumipes* (Prenter et al. 2010a, b) in laboratory climbing trials. In the orb-web spider *Nephila clavipes*, in which the male body size distribution includes the threshold size of 7.6 mm, the predicted advantage of males of intermediate sizes was found (Vollrath 1980). In the study of climbing speed in the orb weaver *Leucauge venusta*, the body size range was mostly above 43 mg as both males and females were included (Moya-Laraño et al. 2007a). As predicted by the GH, body size was inversely related to climbing speed. In fact, no study has yet yielded results in opposite direction to the predictions of the updated GH, and one non-published study even found evidence for smaller males having better mobility and mating success (Linn 2001). The reason why the predicted relationship between body size and climbing speed was not found for some species is not clear. Apart from gravity effects, morphological aspects such as absolute and relative leg length ought to be important for achievable running speed on structure of any angle of incline (Foellmer et al. 2011). In addition, performance itself is a characteristic based on the metabolic capacity of organisms and can evolve, at least to some extent, independently of body size (Calsbeek and Irschick 2007; Irschick et al. 2008; Lailvaux and Irschick 2007).

Findings that large male size confers higher mate search success or higher climbing speed was initially interpreted as evidence against the GH (Foellmer and Fairbairn 2005), but the Curvilinear GH has provided an explanation for the pattern (see above). Another implication of these studies is unresolved; however, we still do not have a good understanding about which factors drive the evolution of male body size below the thresholds predicted by the curvilinear GH and bridging GH (Morse 2014). The involved processes may be species specific. What has emerged from the body of literature available to date is that most likely gravitational forces have been the key factor uncoupling the evolution of male and female body sizes, breaking the genetic correlation between the sexes for body size expression (Foellmer and Moya-Laraño 2007; Moya-Laraño

et al. 2009). Below, a general trade-off model is offered that may help explaining these species-specific differences.

A General Trade-Off Model to Explain the Evolution and Maintenance of Extreme SSD

The entire body of hypotheses, models, and empirical evidence on the evolution and maintenance of extreme SSD can be merged into a single graphical model similar to that in Corcobado et al. (2010), as depicted in Fig. 1. Depending on the strength of the selective pressures acting on

each sex, and a size-dependent trade-off involving mobility/viability and other selective pressures, one could explain the evolution of extreme SSD from monomorphism (i.e., males and females of similar size) and even the reversal to monomorphism from clades in which extreme SSD had previously evolved (Hormiga et al. 2000). Assuming that fecundity selection favoring larger females will trade-off with their mobility either during bridging or during climbing, any selective pressure that demands higher female mobility (e.g., high dispersal adult rates) will counter the evolution of female gigantism from fecundity selection or even reverse gigantic females to clades with smaller females. In males, traits

Gravity Hypothesis, The, Fig. 1 A general trade-off model explaining the evolution of extreme SSD in spiders. *Black filled circles* show the original hypothetic ancestral situation in which both males and females were of similar size. *Horizontal dotted arrows* show the strength of selection favoring smaller sizes (*wider arrows* mean stronger selective pressures). *Vertical solid arrows* show the strength of selective pressures favoring larger sizes. Evolution occurs along the trade-off line in the direction

determined by the balance between the two types of selective pressures. If large size from fecundity on females is favored and small size for mobility or viability is favored in males, extreme SSD evolves (*red arrows and circles in top panels*). When mobility on vertical surfaces favors smaller female sizes or large male sizes are favored from other competitive abilities, reversal to monomorphism can evolve (*blue arrows and circles in bottom panels*) (Redrawn from Corcobado et al. (2010))

favoring smaller sizes, such as bridging, climbing, or even viability, when male mortality is much higher than female mortality (the DMM), will trade-off with other male competitive abilities favoring larger sizes (e.g., mobility on flat surfaces, male-male contest competition). When reaching females involves higher male mobility in tridimensional habitats, smaller males will be favored. Strong fecundity selection acting on females and strong selection for mobility on tridimensional habitats on males will lead to the evolution of extreme SSD. However, according to the update of the GH (Corcobado et al. 2010), bridging must be a much more important trait associated with the evolution of small body size than climbing. When these selective pressures on one or both sexes are relaxed, evolution on the opposite direction along the trade-off line occurs, possibly leading to a reversal to monomorphism.

Future Perspectives

Several of the predictions of the extended GH remain to be tested. For instance, a post hoc model for the curvilinear GH (Moya-Laraño et al. 2009) predicts that at smaller sizes the frequency of leg (muscle) striding is constant, at intermediate sizes is inversely proportional to size, and at larger sizes becomes inversely proportional to the square of size, which explains when a negative relationship between climbing and body size arises. Detailed laboratory climbing experiments with high-speed cameras are necessary to test the above predictions. The biomechanical model accompanying the bridging GH (Rodríguez-Gironés et al. 2010) predicts that silk produced in minor ampullate glands in spiders will support much lower weights than those typical of gigantic females and that large spiders will drop to the ground if hanging from such silk. Tests of silk properties released by spider males are needed. Also, evidence that the above silk is economically cheaper than that produced from major ampullate glands (e.g., for capture webs) could be granted. Despite the fact that the “ghost of the evolutionary past” could be at play, further evidence that smaller bridging males have an

advantage finding mates in the field would be appropriate (Linn 2001). Finally, a few of the predictions in the general trade-off model of Fig. 1 could be tested. For instance, documenting the selective pressures in the field (e.g., differential mortality between the sexes – De Mas et al. 2009) in species living in tall habitats versus those living in short habitats could show whether the DMM and the GH interact (e.g., is differential mortality stronger in tall habitats?), possibly leading to the evolution of males even below the size threshold predicted by the updated GH. Or, in species that live in tall habitats and use bridging as a dispersal mechanism, is there a negative relationship between adult female body size and the propensity of females to relocate their webs? In other words, is there evidence of a trade-off between body size and mobility from bridging?

Conclusion

The original gravity hypothesis predicted a negative relationship between climbing ability and body size. However, new data and updates of the hypothesis showed that the relationship between climbing speed and body size was parabolic, with an optimal climbing speed at intermediate sizes. Furthermore, a biomechanical model shows how another mechanism of spider dispersal, bridging, can actually be behind the evolution of extreme SSD, giving rise to the bridging GH. This last hypothesis has a stronger predictive power than all previous hypotheses to explain the observed patterns of SSD across spiders. A size-based trade-off graphical model has been proposed here to explain the evolution and maintenance of extreme SSD, which integrates most of the current mechanisms favoring large or small body sizes in both males and females. Further data are needed to fully understand the GH.

Greater Polygyny Selects for Greater Risk-Taking

Definition

When men can have multiple female partners, male mating competition increases, leading to riskier behavioral strategies.

Introduction

Most mammalian species are polygynous, where a male can simultaneously have several female mates (Reichard and Boesch 2003). In polygynous species, male reproductive success is

more highly skewed than female reproductive success, both because of high-status males with multiple mates, and because fewer potential partners are available to lower status males. The greater intensity of intrasexual selection increases male risk-taking in the competition for resources and status.

Sexual Selection and Polygyny

Sexual selection helps explain sex differences in psychology and behavior, including greater male tendencies for risk-taking, competitiveness, and sensitivity to social hierarchy (Cronin 1991). Males compete more intensely for female sexual partners in most animal species because females usually invest more in offspring and are therefore selected to be more discriminating in selecting mates (Bateman 1948). Male mating competition can involve fights with other males for rank or territory; it can also involve competition over traits and displays that females prefer in their mates. Males succeeding in these competitions have more offspring, shaping traits that foster such success, even if those traits also have detrimental consequences (Darwin 1871).

In polygynous species, some males will have many offspring while many others will have none, creating powerful selection pressure for traits that lead to success in mating competition at the expense of longevity (Plavcan 2000). The degree of polygyny is analogous to male reproductive inequality. In highly polygynous species, a few males will have many offspring, whereas many others will have none (Reichard and Boesch 2003). This highly skewed reproductive success creates powerful selection pressure for traits that lead to success in mating competition. Such selection pressure has produced elaborate ornaments (such as the peacock's tail) and armaments (such as a deer's antlers), all with substantial costs. The longevity gap between males and female vertebrates is highest among polygynous species (Clutton-Brock and Isvaran 2007).

Primates vary considerably in the degree of polygyny; humans have a moderate degree of polygyny (Betzig 1986). Still, men's reproductive

success is more variable than women's reproductive success, resulting in male mating competition as a potent force of selection. Polygyny occurs in the vast majority of cultures (84%) documented by anthropologists (Ember et al. 2007). The heightened degree of male mating competition in polygynous cultures leads to higher levels of risk-taking, with resulting detrimental consequences for mortality (Kruger 2010).

Conclusion

Higher degrees of polygyny correspond to an effectively higher (more male biased) sex ratio, increasing the intensity of male mating competition and associated risk-taking.

Greater Risk-Taking and Status

Definition

The greater the inequality in social status and the greater effect that social status and relative position has on reproductive outcomes, the greater risk-taking will be, especially for men. Greater uncertainty in important aspects of life will also increase risk-taking.

Introduction

Patterns of risk-taking in relation to social status concerns can be understood through the framework of life history theory. Greater risk-taking is associated with greater uncertainty and inequality in reproductive success.

Status Competition and Risk Taking

Life history theory explains variation in behavioral and physiological strategies as partially contingent on conditions in the developmental environment. Individuals developing in relatively uncertain environments will develop riskier behavioral strategies to take advantage of possibly fleeting opportunities (Chisholm 1999). Humans living in chronically risky and uncertain environments are more likely to experience earlier menarche, earlier ages of reproduction, and higher reproductive rates (Chisholm 1999). Community college students who expected shorter life spans and saw the future as less predictable had a higher frequency of risk-taking (Hill et al. 1997).

Neighborhood homicide rates are predicted by neighborhood life expectancy (controlling for the effects of homicide) and neighborhood income inequality (Wilson and Daly 1997). Risky behaviors may have facilitated early reproduction before death occurs, steep discounting of future outcomes is a response to environments where the probability of receiving delayed benefits is uncertain or low, and the expected benefits of safer courses of action are negligible (Wilson and Daly 1997). Urban middle school students who lived in more dangerous neighborhoods were more oriented to present rewards, and time perspectives predicted rates of interpersonal violence and property crimes (Kruger et al. 2008).

When competition for resources and social status is more intense, greater tendencies for risk-taking are evident. The shift in the male allocation of effort from somatic to mating to parenting over the life course helps to explain the pattern of risky behavior underlying the peak in sex differences in mortality from behavioral causes across the life span (Kruger and Nesse 2006). The peak in risky behaviors during young adulthood corresponds with entrance into mating competition (Wilson and Daly 1993).

Men compete for social status and resource control, as these are characteristics valued cross-culturally in intersexual selection (Buss 1989). In ancestral times, men who controlled more resources partnered with younger women, partnered with more women, and produced offspring earlier (Low 1998). Even in relatively egalitarian foraging societies, men with higher status have greater sexual opportunities (Chagnon 1992; Hill and Hurtado 1996).

Over the course of human history, variance in male wealth and power increased through sociopolitical arrangements and intergenerational transfer (Smuts 1995). Where there is greater variation and skew in male social status and resource control, there will be greater competition for positions of power and status. Relative socioeconomic position has a stronger influence on mortality rates for men than for women (Bopp and Minder 2003; Kruger and Nesse 2006). Increased uncertainty in economic opportunities and greater variability in males social status and resource control within

populations are associated with elevated male mortality rates (Kruger and Nesse 2007). The degree of the economic disparity across a population directly predicts the extent of excess male mortality (Kruger 2010).

The degree of male risk-taking is also directly related to male reproductive inequality. The higher the degree of polygyny in a population, where high status men are better able to attract and/or retain multiple female partners, the higher the effective sex ratio will be. For every woman who is polygynously mated, there is one less woman available to other men. Higher degrees of polygyny are associated with greater consequences of male mating competition (Kruger 2010).

Conclusion

Patterns of risk-taking can be understood as an aspect of human life history. Higher levels of risk-taking are evident when important life outcomes are unpredictable and when there is greater inequality in attributes that are historically related to reproductive success.

Green Beard Effect, The

Definition

A concept in social evolution theory where a single gene or a set of multiple tightly linked genes has two phenotypic effects: a trait that allows other individuals to recognize carriers of the gene (such as growing a greenbeard) and

a behavioral trait whereby altruistic acts are directed toward others recognized as carriers.

Introduction

In 1964, William Hamilton published two classic articles on the evolution of social behavior, seeking understanding of the evolution of altruistic traits. The first of these articles (Hamilton 1964a) focuses on mathematical theory. The second paper (Hamilton 1964b) discusses the implications of the theory and gives it further biological context. In a brief section of the second paper, Hamilton also discusses a hypothetical “supergene affecting (a) some perceptible feature of the organism, (b) the perception of that feature, and (c) the social response consequent upon what was perceived.”

Although Hamilton first described the idea, the popular name “greenbeard” comes from Richard Dawkins (1976) who illustrated the idea with an intuitively appealing and visually memorable example where the perceptible feature of the organism is a greenbeard, encoded by a gene such that its carriers not only have greenbeards, but they also tend to be selectively altruistic toward others with a greenbeard. It is not difficult to envision how such a gene can be successful in a population even if the altruistic act is costly, as long as the benefits to the recipient are sufficiently high. Consider a simple and extreme example of a greenbeard gene that causes its carrier to save five other carriers of the same gene from certain death while sacrificing itself: the net effect is of course that a larger number of gene copies remain in the population due to the altruistic act, despite the death of the altruist.

The Green Beard Effect and Kin Selection

Richard Dawkins (1976) used the idea of a greenbeard gene to direct readers into the right mind-set for grasping the empirically more important concept of *kin selection*. Once one realizes that greenbeard genes can become more common in the population by helping identical copies of themselves carried by other greenbeards, it is a

relatively small step to understand that similar logic applies even if it is not guaranteed that the recipient of help carries a copy of the same gene. In kin selection theory, it is more likely (although not certain) that close relatives will carry identical copies of the same gene, when compared to random members of the population. In other words, helping fellow greenbeards and helping close relatives are two different ways a gene can help copies of itself via altruistic behavior. The greenbeard effect is therefore useful as a thought experiment that helps us reason about other evolutionary phenomena.

The greenbeard effect is distinct from *kin recognition*, in which individuals may share a phenotypic marker coded by a marker gene (Gardner and West 2010). In contrast to greenbeard genes, such a kin recognition marker gene need not be directly linked to any behavioral trait. It simply serves as a signal that suggests two carriers may be closely related. And if the carriers are closely related, they are likely genetically similar across all of their genome, not just the marker locus. A greenbeard gene, in contrast, need not indicate similarity elsewhere but at the greenbeard locus and closely linked loci. A greenbeard gene may of course be shared by genealogical relatives, but the greenbeard effect is not reliant on this.

Some authors nevertheless consider the greenbeard effect to be a subset of kin selection. Although the word “kin” suggests interaction with genealogical relatives, the more general theory of kin selection accounts for genetic similarity arising for any reason, including greenbeard effects (Gardner et al. 2011). It is not likely that a full consensus will be found on the precise meaning of the term “kin selection,” but it is useful to be aware of the different uses of the term.

Are Greenbeards Stable?

Intuition might suggest that greenbeard genes are unstable over long evolutionary timescales in two ways, of which only one is correct.

Let us consider first the incorrect idea: Recall that a greenbeard gene does not necessarily indicate similarity elsewhere in the genome but at the greenbeard locus. Given that the gene causes

behavior which is costly to its bearer, it is easy to imagine that there would be selection for a modifier elsewhere in the genome to suppress the greenbeard gene entirely – after all, these genes depend on the survival of the same body, and they pay the cost of altruism, but are not particularly likely to be present as copies in recipients (other greenbeards). But a moment’s thought shows that such a modifier would typically not spread. Imagine a population where everyone is a greenbeard, implying that benefits have outweighed the costs for the greenbeard in the past when it has spread in the population. Now if a mutation elsewhere in the genome suppresses the greenbeard gene, what happens? Carriers of this new mutation will not pay the cost for altruistic behavior. But the flipside is that they will no longer have greenbeards and will no longer benefit from the altruism of other greenbeards. The original greenbeard gene would only have spread if greenbeards were on average fitter than non-greenbeards. The new mutant is for all practical purposes now a non-greenbeard and hence will not be selected for. This is why suppressors of greenbeard genes are typically not positively selected, assuming the greenbeard gene was selected for in the first place (see Ridley and Grafen 1981; Biernaskie et al. 2011).

The more acute problem facing greenbeard genes is that of so-called *falsebeards*. A falsebeard is an individual with a greenbeard, but who does not behave altruistically toward others. Contrary to the modifier gene described above, a gene that suppresses the altruistic behavior but not the beard is at an advantage because its bearer still receives altruism from greenbeards (who cannot distinguish it from other greenbeards) but does not pay the cost of altruistic behavior itself. Falsebeards are an important reason for why greenbeards are expected to be rare in nature and are likely to only be found in situations where the link between beard and behavior is very difficult to break, so that falsebeards are unlikely to arise.

Greenbeards in Reality

So far we have considered greenbeards mostly from a conceptual point of view, and indeed

they were originally conceived as a thought experiment; perhaps unlikely in nature but nevertheless helpful in thinking clearly about reality. Despite their seeming improbability, several examples of greenbeards have by now been discovered (reviewed in Gardner and West 2010; Madgwick et al. 2019). Most of these empirical examples have been found in microorganisms. It has been hypothesized that this is because the potentially simpler link between genotype and phenotype in microorganisms may prevent the evolution of falsebeards (see above), which would require a decoupling of the signal and behavior (Gardner and West 2010). It is likely that in humans and other complex multicellular organisms with complex genotype-phenotype links greenbeards would be highly vulnerable to falsebeards. There is also some disagreement on published empirical examples of greenbeards, and a recent review suggests that they all fall short of fully conclusive evidence for classification as greenbeards (Madgwick et al. 2019).

The prevalence of greenbeards in nature also depends on how strict we are with the definition. For example, Dawkins (1986) used the greenbeard effect to illustrate the evolution of exaggerated sexually selected traits, such as a peacock's tail which would typically be thought of in terms of, e.g., Fisherian runaway selection. Imagine there is some preference for long tails among females. Such a preference implies that a son of a long-tailed father is likely to carry not only genes for a long tail but also genes – inherited from his mother – for a preference for long tails. The latter genes may not be expressed in males but can nevertheless be carried and passed on by males. As a consequence, the long tail of the son acts as a greenbeard-like signal that he is likely to carry genes for long tail preference. The outcome is a system where genes for a signal (long tail) and for fitness-enhancing behavior (choosing to mate with males with long tails) become linked. Genes for choosiness in females are helping copies of themselves by choosing long-tailed males. And if genes for preferring long-tailed males become common in the population, then long-tailed males will be successful and will also become more common in the population.

Another real-world example where the greenbeard effect can clarify our thinking about nature is the evolution and maintenance of sexual reproduction. It is often thought that sex is a costly way to reproduce because a parent passes on only half of its genes to the offspring, giving away 50% of the genetic representation in the offspring to the other parent. If the parent simply cloned itself, it would pass on 100% of its genes. But consider this from the perspective of a hypothetical gene for sexual reproduction. Individuals that do not carry this gene do not reproduce sexually. Hence the act of sexual reproduction is in itself a marker for carrying this gene, analogous to a greenbeard. By mating with another sexually reproducing individual, the parent is helping copies of the gene for sex in the other parent (Lehtonen et al. 2012). Although this suggests that such a cost of “genome dilution” may be illusory, there are many other evolutionary costs to sexual reproduction which is why its prevalence remains one of the big mysteries in evolutionary biology (Lehtonen et al. 2012).

It is reasonable to ask if these two examples are really instances of greenbeards. The answer depends on how far one is willing to extend the definition. But perhaps it does not matter. The original spirit of the greenbeard effect was a thought experiment that helps us reason about nature, and so it does in these questions of sexual selection and sexual reproduction.

Evil Beards

Greenbeards are typically thought of as altruists, but Hamilton (1964b) noted that “if an individual can be attracted towards likes when it has positive effects -benefits- to dispense, it can presumably be attracted the other way, towards unlikes, when it has negative effects to dispense.” If a greenbeard is able to selectively harm those individuals that do *not* carry copies of the greenbeard gene, the outcome is that the non-greenbeard competitor decreases in relative frequency in the population, and conversely the greenbeard gene increases in frequency – again, provided the costs to the evil greenbeard are not too great, and the costs to the individuals being harmed are great enough.

However, the evolutionary dynamics of harming greenbeards are more complicated than those of helping greenbeards, and they tend to be positively selected only once they have reached a high enough frequency in the population (Gardner and West 2010).

Conclusion

The greenbeard effect was originally devised as a thought experiment that clarified reasoning about the evolution of altruistic behavior. It has subsequently become a growing field of study, from a theoretical as well as empirical perspective. The biggest threat to the long-term evolutionary stability of greenbeards is “falsebeards,” in which the signal (greenbeard) is retained, while the altruistic behavior is abolished. For this reason, greenbeards are expected to be found in settings where it is difficult to decouple the greenbeard signal and associated behavior by mutation. Although initially thought to be implausible, examples of greenbeards have been found in nature, particularly in microorganisms.

Definition

Humans are a highly social species, with an evolutionary history of living in cohesive and structured groups. There are many psychological processes specialized for adaptively dealing with intragroup and intergroup phenomena.

Introduction

Animal species vary in the extent to which they are social, and there is broad consensus among researchers that humans are a highly social species. Human sociality is evident throughout the lifespan. Humans are an altricial species, meaning that infants are not capable of sustaining themselves and require a high level of care for a prolonged period. As children grow, acquiring the skills necessary to survive requires a great deal of learning from the older generation and peers. And unlike most mammal species, humans tend to pair bond, meaning that couples form lasting relationships within which reproduction and rearing of children tend to occur. More generally, people of all cultures spend a substantial amount of their waking hours socializing with others, and contemporary psychological evidence indicates that humans have a strong motivation to maintain close relationships with a handful of others (Baumeister and Leary 1995).

Human sociality goes beyond the small circle of immediate family and close friends. Evidence indicates that humans are adapted to living in groups of dozens of individuals (Dunbar 2004). These groups would have presented different kinds of opportunities and threats, as different social interactions are associated with different types and degrees of benefits and costs in terms of survival and reproduction. Accordingly, many aspects of human social cognition are expected to exhibit functional specialization, with distinct psychological mechanisms for optimally managing the diverse kinds of social relationships and interactions (Kurzban and Leary 2001). A crucial part of human social psychology is that, in addition to individual-based thoughts and feelings (e.g., liking one person more than another based on familiarity, attractiveness, reciprocal exchange, etc.), there exist group-based thoughts and feelings (e.g., favoring one person over another, based solely on group membership, separate from individual-based preferences). Group-based psychological processes are likely to have emerged due to the evolutionary benefits of within-group cooperation, benefits which are further bolstered by out-group exploitation, resulting

in the evolution of between-group competition (Kurzban and Leary 2001). Over time, humans best able to cooperate with in-group members and outcompete rival groups would have been most reproductively successful, resulting in a species-wide tendency to be tribal. There is plenty of psychological evidence for humans' propensity to favor in-group members over out-group members (Tajfel 1982).

While *group living* technically encompasses the entirety of human sociality – including pair bonding, parenting, sibling relationships – this chapter focuses on aspects of human psychology associated with “groups” as typically conceptualized in psychology (i.e., collectives of unrelated individuals who cooperate and sometimes engage in competition with other similar collectives). Those other aspects of sociality (e.g., pair bonding, parenting) are covered in other chapters of this volume. For the sake of organization, the remainder of the chapter is divided into two major sections: within-group processes and between-group processes.

Within-Group Processes

To reap the benefits of group living, ancestral human collectives needed to achieve coherence and stability. In this section, various aspects of intragroup processes that were pivotal for successful group living are reviewed. These include (a) being able to navigate social hierarchies, (b) being able to work together cooperatively, and (c) being able to identify nonreciprocators and noncontributors in order to exclude them. As noted above, this section reviews dynamics among individuals in a group that are either distantly related or not related at all.

Navigating Social Hierarchies

For group living to be successful, social order and intragroup structure are essential. In situations where resources (e.g., food and mates) are limited, established social structures minimize the need for confrontation that can arise from competition for these resources. Of course, there is competition for position on the hierarchy, as level of rank in a

social group is directly associated with mate allocation, food allocation, and territory. High-ranking members can be awarded with disproportionately high levels of resources, mates, and territory. In contrast, low-ranking members are likely to get much less resources, mates, and territory. It is therefore a good strategy to attempt to gain the highest possible rank that is available.

There are two techniques that can be deployed to establish social rank. The first one is *social dominance*, the use of force and intimidation in order to induce fear and subordination from those who are ranked lower (e.g., a “bully” who asserts his status through agonistic encounters). The second is *prestige*, the ability to impress others by demonstrating high-level skills and abilities. For example, Mother Theresa was able to establish a high social ranking and was known worldwide, not due to her aggressiveness and dominance, but by her prestige alone.

Social Dominance

Social dominance is a form of establishing social rank that has been observed in many social animal species and particularly in primate species, with dominance being typically achieved with acts of aggression (Trivers 1985). However, humans do not display acts of dominance through physical conflict alone. Social dominance can be achieved by having control over the extent to which others have access to resources, mates, and their own well-being. The threat of losing any of these resources results in lower-ranking individuals being subordinate to higher-ranking individuals who hold this control. Examples of those resources that could be deprived include the loss of resources for their wellbeing, their children, or their livelihoods (Cheng et al. 2010). Despite the negative connotations associated with social dominance, there are also positive aspects. For example, dominance has been associated with high levels of agency and can be indicative of better leaders (Cheng et al. 2013), with trait dominance being a predictor of leadership (Lord et al. 1986).

Prestige

The second form of navigating social hierarchies and gaining social rank is through obtaining

prestige. This involves having a high social standing and commanding a high position in people's minds. Instead of gaining social rank through power and evoking fear, prestige involves being influential. Those who possess prestige tend to be listened to and are able to convey heavily-weighted opinions that are influential rather than being obeyed. Using the example of Mother Theresa, her social standing was based on her influential practices, rather than being able to force her views and opinions on others.

Henrich and Gil-White (2001) provided an evolutionary explanation for why those with prestige hold a high social standing. Human cultural capacity, meaning the capacity for intergenerationally stable social transmission created a new selective environment that favored those who promoted transmission. Social learning through social transmission is adaptive, particularly in group settings, as it saves the learners the cost of individual learning. Once the human cultural capacity was in place, it favored the propensity to identify and copy models who are considered as being better than average. Put more simply, it makes more sense to be able to identify and prefer to learn from those people who demonstrate that they have a high skill level. Copiers (i.e., those that want to learn) therefore evolved to seek out and prefer models who provide this higher level of learning and will, reciprocate by cooperating and offering a range of benefits. This means that those preferred models have a certain level of prestige from the perception that their copiers have of them. Moreover, the level and status of copiers is directly associated with the level of prestige that the model holds. As the level of expertise that a copy model holds is directly related to their own level of prestige and social ranking, this means that there is also an incentive, between models, to outperform each other.

Cooperation

Humans are remarkably adept at working cooperatively and forming social groups. In addition to cooperation among kin, there are other various kinds of cooperation among nonkin including

direct reciprocal altruism, also known as social exchange, and indirect reciprocal altruism, which can be associated with recognition of values and formation of friendships.

Social Exchange

Social exchange, also referred to as reciprocal altruism and dyadic cooperation, is the practice of mutual provision of benefits on the assumption that the receiver will be compliant and reciprocate either immediately or in the future. This practice is observed among humans and only a small number of nonhuman species, such as chimpanzees and baboons. Moreover, the ability to create social exchanges with a variety of different goods and services is an exclusively human trait (Cosmides and Tooby 1992). In situations where social exchange takes place between two individuals who are unfamiliar with each other, the conditions of the exchange are likely to be explicit; in contrast, in situations where individuals know each other, conditions for social exchanges are likely to be implicit and rely upon social norms (Cosmides and Tooby 2005). Furthermore, if social exchange occurs between familiar individuals, reciprocation can be delayed with less urgency for it to be fulfilled. In these social exchanges, the behavior of the receiver is normally factored into deciding whether future exchanges should take place (Cosmides and Tooby 2005).

As social exchange goes beyond associative learning, such as classical and operant conditioning, researchers have proposed that humans have a specialized evolved capacity to engage in social exchange. This suggests that social exchange may be a product of functionally specific cognitive mechanisms, designed to predispose humans to engage in seeking and creating social contracts (Cosmides and Tooby 2005). In order for humans to possess cognitive mechanisms for social exchange, a further ancillary mechanism designed to detect cheaters would be required (see below). Indeed, this view is supported by neurological evidence showing that cheater detection can be selectively impaired and is closely associated with other forms of similar reasoning (Stone et al. 2002).

Friendship

Distinct from social exchange, a direct form of reciprocal altruism, is Tooby and Cosmides's (1996) model of psychological engagement, commonly known as friendship. People possess skills and/or attributes that are valuable to others. During the course of engagement, these individuals create externalities (outward displays) that, as a by-product, can be perceived positively or negatively. As others are likely to seek out those with positive externalities, this can motivate individuals to display positive externalities and minimize negative externalities. For example, it is likely that those who frequently demonstrate good hygiene practices are much more likely to be favored as a potential friend in place of those who demonstrate poor hygiene practices.

This situation is therefore likely to cause adaptations for individuals to seek out those who are sources of these qualities. Thus, a feedback loop is created, whereby *X* seeks out *Y* due to their positive externalities, and *Y* is therefore interested in *X* by virtue of the fact that *X* is interested in *Y*'s welfare (Kurzban and Leary 2001; Tooby and Cosmides 1996).

What differentiates the psychological engagement model from reciprocal altruism is that it does not rely on the direct social contract that one individual will benefit from the other's generosity on the condition that it will be reciprocated in the future. Instead, it is based on the notion that an individual can be valued while pursuing their own goal and at no cost to themselves. The value is therefore not due to exchange of goods but due to individuals valuing each other.

Cooperation and the Supernatural

One of the puzzles of human cooperation is why unrelated individuals would help a stranger who they are likely to never meet again and where reputation effects are absent. Johnson and Krüger (2004) suggested that throughout our history, fear of the supernatural has deterred defectors from avoiding helping others, even if they are strangers, for the common good. This is supported by the fact that supernatural beliefs are universal among human societies and there are associated taboos for not contributing to the common good.

Furthermore, punishment for noncooperation could be the possibility of being deprived of privileges in the afterlife, such as entrance to heaven.

Social Exclusion and Stigmatization

While it is important to work cooperatively as a cohesive group, part of its success will be down to making sure that all members are able to contribute appropriately and that all members do contribute. Even if a group does work cooperatively, there are a number of instances when this can still fail. These reasons include, but are not limited to, those who do not make good social exchange partners or potential friends, those who do not cooperate in the wider context of a group setting, and those who pose a health risk due to being perceived as potentially ill.

Due to the consequences of individuals not contributing or being fit to be part of the group, it is likely that a suite of psychological mechanisms have evolved to promote social exclusion. Kurzban and Leary (2001) proposed that stigmatization originated not from an individual being negatively evaluated for idiosyncratic reasons, but because that individual possesses characteristics or exhibits behaviors that are collectively disagreeable to the group. Kurzban and Leary argued that humans have evolved three specific mechanisms through which social exclusion can occur. The first is dyadic cooperation, a suite of adaptations designed to avoid those who would either make low-value partners, be a greater cost than benefit to the group, or does not possess some or all of the qualities valued to that particular group. The second is the importance of selecting members that meet the standard of the group and exploiting those who do not (this section will only take into account standards for group selection). The third is parasite avoidance, a suite of adaptations that are designed to detect, avoid, and prevent prolonged contact from those that have perceptual cues associated with disease threat.

Dyadic Cooperation

Dyadic cooperation encompasses kin selection, reciprocal altruism, and group-based models. In a hunter-gatherer scenario, a successful hunter may provide their surplus to an unsuccessful

hunter, in order to bridge a shortfall in the supplies that they may have. However, the costs of benefit delivery are only acceptable if the receiver is likely to reciprocate the gesture in the future. This means that in order for this type of cooperation to be successful, cheaters and low-value group members, who are unlikely to be able to reciprocate in the future, must be excluded (Cosmides and Tooby 1992).

In addition to reciprocal altruism, friendship selection also plays a part in the cooperation from those who are considered friends, and the social exclusion of those who are not accepted as friends. Tooby and Cosmides (1996) suggested that humans only have a limited amount of time to form and build friendships. As such, affiliations with some people may mean missed opportunities for forming friendships with others. Particularly for more popular members of a group, this may also lead to the rejection of some due to receiving more offers of friendship than one can have time for.

Restrictions for opportunities with both friendships and social exchange mean that decisions should be made wisely. Kurzban and Leary (2001) suggested that there are three categories that can be used for exclusion from cooperative relationships. The first is unpredictability, relating to whether an individual recognizes that opportunities for social exchange exists. In order to engage in social exchange or to engage in engagement, it has to be possible to coordinate with the other individual and to be able to predict their intentions. Not being able to predict someone's intentions can make these practices very difficult as there is an issue of uncertainty. Unpredictability can occur when they violate social norms. For example, someone who engages in self-destructive behavior (e.g., attempting suicide) could be seen as unpredictable. Indeed, engaging in behavior that deviates from the norm is used to diagnose many mental health issues. Therefore, if an individual is seen as being unpredictable, this presents an element of uncertainty in terms of their future value, and can be a cause for social exclusion.

The second reason for exclusion, both in social exchange and in friendship, if an individual has

poor prospects and offers little capital both in the social and economic sense. Examples include individuals who could be perceived as financially poor, be ill, elderly, or have little social connections. Indeed, there is evidence to show that those who are lacking in social and economic resources are among the most stigmatized (Phelan et al. 1997).

The third is the perception of cheaters, those individuals who take part in a social exchange and do not reciprocate. As discussed, in order for a reciprocal system to be adaptive, it would have had to evolve ancillary mechanisms that are designed to detect cheaters. It is therefore likely that individuals who do cheat will be excluded both from social exchanges and friendships. The term cheating can be applied to those who seek to obtain benefits from goods or services that they need, to satisfy a chemically rewarding substance, or to fulfil a sexual appetite. It is likely that those who are detected as cheaters are actively punished, rather than simply being avoided like those individuals with poor prospects.

Selection for Within-Group Membership

The strength of the group is dependent on the level of cooperation within the group. It is therefore adaptive to ensure that group members are both competent, are able to advance the interests of the group, and willing to sacrifice for the good of the group. Conversely, it is likely that there are psychological mechanisms that have evolved to detect and exclude individuals who do not meet the criteria or standard that the group expects. For example, it is important that all group members both share the benefits of the group in proportion to their social rank and equally share the costs and risks (Kurzban and Leary 2001). It is also important that these individuals conform to social norms and expectations that the group may have. If a group member does not meet these criteria and standards, that member is likely to be removed from the group (Neuberg et al. 2000). Moreover, public displays could be used to shame an individual and ensure that all members of the group are aware of their exclusion, with actions such as locking them in a public stockade.

Parasite Avoidance

As disease has been one of the biggest threats to human survival, it has been proposed that humans, as well as animals, have evolved a behavioral avoidance system (BIS) that is designed to detect and avoid perceptual cues associated with disease threat (e.g., Schaller and Park 2011). As diseases cannot be directly perceived, this system relies upon perceptual cues that are imperfectly correlated with disease threat. Put more simply, not all perceptual cues will mean that a disease threat is present. Due to this imperfect correlation, the BIS is overinclusive, meaning that it is more likely to activate when there is no disease threat present (false positive) rather than the more costly chance of not activating when there is a disease threat present (false negative). Due to the close proximity of groups, it is likely that any disease threat would have disastrous consequences to the community. In ancestral times, many humans lived in small close-knit communities, meaning that any disease could have grave consequences if any of the key members of the group were to become ill. Common effects of disease, such as fatigue and fever, would incapacitate any number of individuals who would then not be able to contribute to the group. The worst case scenario is that one or more individuals die as a result of disease. As such, it is highly likely that those individuals who do appear to suggest disease threat (e.g., visible sores, vomiting, etc.) are likely to be excluded and avoided. Moreover, due to the overinclusive nature of the BIS, it is also likely that those individuals who appear abnormal but carry no disease threat may also be excluded (e.g., obese individuals; Van Leeuwen et al. 2015).

There are functional explanations for why social exclusion and stigmatization of certain individuals has become part of our evolutionary make up. Those individuals who would make low-quality group members and would form poor relationships, either due to cheating, lack of social or economic resources, or due to being perceived as a type of threat, are likely to be excluded. Although these three categories have been presented as being distinct, an individual maybe excluded and stigmatized for being considered

as possessing more than one of these categories (e.g., obese individuals; see Van Leeuwen et al. 2015).

Between-Group Processes

Groups can often achieve more than isolated individuals can. This is true of groups in preindustrial societies (e.g., cooperative hunting, childcare, and farming) and has only become intensified in industrial societies (e.g., modern manufacturing). Clearly, cooperating in-groups often confer many advantages, and this was likely a key driving force underlying the evolution of psychological capacities pertaining to within-group processes discussed above. At the same time, there is evidence that psychological processes underlying groups have also been shaped by a long history of intergroup conflict. There is archaeological and anthropological evidence indicating that intergroup violence has a long evolutionary history within the human lineage (Bowles 2009). Throughout history, as much as 20–30% of men may have died from intergroup violence, and this is also true of contemporary hunter–gatherers (Keeley 1996; Pinker 2011). For these reasons, it has been suggested that humans possess “tribal instincts,” a set of psychological processes specialized for dealing with antagonistic intergroup situations (Van Vugt and Park 2010). These tribal instincts include the propensity to spontaneously divide up the social world in in-groups (us) and out-groups (them), the tendency to favor in-group members over out-group members, and distinctly negative beliefs and attitudes regarding out-group members. Also, these tendencies are flexibly heightened in situations perceived to involve intergroup competition.

Categorization

Humans naturally carve up the social world into various categories, which are partly based on biology but also subject to cultural influences. Some of the fundamental categories that humans routinely perceive and utilize – genders and age categories, for instance – may be due to their adaptive relevance. Quickly categorizing other

individuals in terms of gender and age would allow one to infer important opportunities and threats (e.g., potential mates and potential rivals for mates). Studies have shown that people also tend to categorize others in terms of race (e.g., white vs. black), and this appears to be a manifestation of a deeper psychology of coalitional alliances (Kurzban et al. 2001). A number of studies (with adults and children) have shown that people tend to perceive racial categories as though they are coalitional alliances, but this tendency can be overridden when other, more diagnostic cues to coalitional alliances (e.g., sports team membership, language/accent) are provided (Kinzler et al. 2010; Kurzban et al. 2001). These different types of categories – genders, ages, coalitions – serve different functions and thus deploy different sets of psychological processes. The intergroup processes covered in this section pertain mostly to the psychological processes associated with coalitions. Groups based on coalitional categorizations engage a specific set of psychological responses, particularly in competitive contexts.

Intergroup Psychology

Social psychologists have tended to use the term “group” somewhat loosely, to include common social categories such as genders and ages. However, groups are cohesive collections of individuals capable of cooperating toward common goals, and this definition narrows down the range of actual human groups. And of those, only a subset – those reminiscent of coalitions – activates intergroup psychological processes. So which categories are experienced as coalitional groups? As Kurzban et al. (2001) argued, human tribal psychology should be sensitive to “(i) patterns of coordinated action, cooperation, and competition, and (ii) cues that predict—either purposefully or incidentally—each individual’s political allegiances” (p. 15387). Examples of the former would be sports teams and opposing militaries. As for cues, examples might include religious affiliation and speech patterns (e.g., languages, accents). This may explain the historically ubiquitous antipathy between different ethnic and religious groups. Of course, social categories that do not fulfill the tribal criteria

(e.g., male/female, old/young, lawyer/architect) may give rise to prejudice and discrimination as well, but this is likely to be for reasons qualitatively distinct from tribal conflict.

Upon perception of people as coalitional in-group and out-group members, perceivers experience positive sentiments (e.g., trust) toward in-group members and negative sentiments (e.g., fear) toward out-group members. The specific emotions experienced will depend on the nature of the out-group and the in-group–out-group dynamic in that specific context (e.g., Cottrell and Neuberg 2005). For instance, out-groups do not simply inspire “negative” feelings, but more specific emotional responses such as fear, anger, disgust, and contempt, depending on their perceived status and the kinds of threat they pose (if any). Thus, what social psychologists refer to as “prejudice” may encompass a varied set of emotional responses and motivational tendencies. Out-groups perceived to pose a safety threat may inspire fear and desires for avoidance. Out-groups perceived to pose a health threat may inspire disgust and desires for exclusion (Schaller and Neuberg 2012).

Stereotypes (traits believed to be associated with specific social categories) also provide a window into the underlying psychology, because stereotypes may also motivate adaptive behaviors, with different kinds of stereotypes potentially driving different kinds of behaviors (Schaller et al. 2003). Commonly held stereotypes tend to be either positive or negative, with in-groups typically being ascribed positive stereotypes (e.g., hardworking, trustworthy, intelligent) and out-groups typically being ascribed negative stereotypes (e.g., lazy, devious, superstitious). Among the negative stereotypes, some connote threat (e.g., untrustworthy) whereas others do not (e.g., lazy). In coalitional intergroup contexts, ascribing threat-connoting stereotypes towards out-groups may be functional, as such beliefs can promote potentially life-saving fear and avoidance. Consistent with this expectation, various lines of research have found that out-groups that can be categorized as coalitions (e.g., races, ethnic groups) do often inspire threat-relevant perceptions, including ascriptions of threat-connoting

stereotypes (Schaller and Neuberg 2012; Schaller et al. 2003).

Intergroup Competition and Conflict

One school of thought in psychology holds that in-group favoritism evolved for its own sake, as it confers survival benefits. Humans necessarily rely on intragroup cooperation for survival, individuals must rely on others for information, help, and resources (e.g., Brewer and Caporael 2006). While this perspective likely accounts for a substantial part of in-group favoritism, there is evidence to suggest that it is unlikely to be the entire story. Thus, another school of thought holds that the evolution of intragroup cooperation was further pushed along by intergroup competition and conflict. For instance, people spontaneously perceive intergroup contexts to be more competitive than interpersonal contexts. Also, in-group loyalty increases when intergroup competition is salient (Van Vugt and Park 2010).

Furthermore, the effect of intergroup competition on in-group loyalty may be sex specific. This is because intergroup conflict may have affected the evolved psychologies of men and women differently. Intergroup aggression has historically involved rival coalitions of males fighting over scarce reproductive resources, a tendency that appears to predate *Homo sapiens* (Van Vugt and Park 2010). As a consequence, this aspect of human coalitional psychology may be more pronounced among men, an idea referred to as the *male warrior hypothesis* (Van Vugt et al. 2007). Across many contexts, it has been found that men are more supportive of intergroup conflict. Also, studies have shown that the effect of intergroup competition on increased in-group loyalty is observed only in men (Van Vugt et al. 2007).

Conclusion

Successful group living has required the evolution several psychological mechanisms specialized for navigating both within-group and between-group aspects of social life. Within groups, group members have a set of standards and expectations that current and new group members should observe.

Cooperation is also an essential part of successful group living, being able to take part in social exchanges with a wide variety of goods and services that are either explicitly expressed or implicitly expected. Beyond social exchange is the formation of friendships, which involve being able to recognize and engage in relationships with people who share positive and/or common values. Equally as important as effective cooperation are the ancillary mechanisms designed to detect those who do not benefit the group and subsequently promote social exclusion.

There are also mechanisms specialized for between-group interactions, which have been driven by a long history of intergroup conflict. These mechanisms include those that impel humans to categorize the world between “us” and “them.” This process is functionally flexible, meaning that it becomes particularly salient in contexts involving intergroup competition. Negative stereotyping tends to be associated with outgroups, whereas positive stereotyping tends to be associated with in-group. These trends towards in-group favoritism have been driven by both intragroup cooperation and intergroup competition for limited resources.

The mechanisms and motivations associated with the within-group and between-group aspects of group living are analogous to the rowing boat races, like the annual race between Oxford and Cambridge. On the one hand, each individual wants to compete to the best of their ability in order to be recognized for their individual contribution and receive the subsequent recognition. On the other hand, members of a rowing team have to work together in order to be able to compete against other rowing teams.

With recent changes in technology, such as the creation and expansion of social media, there have been many fundamental changes to the ways in which groups are perceived and how individuals can communicate on a group level. As already discussed, the term “groups” can be used loosely in social psychology, but it becomes a lot clearer when a group is considered as one that is working towards a common goal. When considering groups that are formed and maintained on social media, many of them meet this criteria. For

instance, groups can be created for a number of reasons that include campaigning towards a cause, sharing an interest, or even just arranging a small-scale event. The long-term effects of this substantial shift in these methods of communication remains largely unknown, but it is likely to fuel research in the coming years.

Group Selection

Dillon Bowen
University of Cambridge, Cambridge, UK

Definition

The hypothesis in evolutionary biology which holds that natural selection acts at the group level. That is, natural selection favors certain groups over others in a population composed of multiple groups.

Introduction

It must not be forgotten that although a high standard of morality gives but a slight or no advantage to each individual man and his children over the other men of the same tribe, yet that an increase in the number of well-endowed men and an advancement in the standard of morality will certainly give an immense advantage to one tribe over another. A tribe including many members who, from possessing in a high degree the spirit of patriotism, fidelity, obedience, courage, and sympathy, were always ready to aid one another, and to sacrifice themselves for the common good, would be victorious over most other tribes; and this would be natural selection.

Charles Darwin, *Descent of Man*, 1871 p. 89

Group selection is the hypothesis in evolutionary biology which holds that natural selection acts at the group level. That is, natural selection favors certain groups over others in a population composed of multiple groups. This hypothesis is often contrasted with individual selection, in which natural selection favors traits which confer fitness benefits at the level of the individual organism. Group selection theorists believe that natural selection acts both among groups in a multigroup population and individuals within a group.

The central idea behind group selection is that intergroup competition creates a selection pressure for intragroup cooperation. Under this hypothesis, a population (the set of all individual organisms competing for some common resource pool) may be divided into groups (subsets of the population composed of multiple individuals whose fitness is interdependent and non-zero sum). When such a division occurs, group members have the opportunity to cooperate with one another in order to exploit mutual gains. Groups which achieve high levels of cooperation will outcompete their more selfish counterparts, garnering a larger share of the resource pool and consequently enjoying greater reproductive success.

If the selection pressure induced by intergroup competition is strong enough, group selection may favor not only intragroup cooperation but altruism. Whereas *cooperation* requires only that a behavior be beneficial for the group as a whole, *altruism* imposes the additional requirement that

such behavior be detrimental for the donor. More precisely, “altruism” refers to any trait or behavior which has the effects of (1) lowering the donor’s fitness relative to its group while (2) increasing the average fitness of the donor’s group members relative to outgroup members. In short, within-group and between-group selection are opposing forces, with selection among individuals within a group favoring selfishness and selection among groups within a multigroup population favoring altruism. Notably, altruism in the context of group selection is distinct from other definitions of altruism, such as that employed by inclusive fitness theory, which will be discussed later. Several notable biologists, psychologists, and behavioral economists, including David S. Wilson, Edward O. Wilson (no relation), Martin Nowak, and Jonathan Haidt, have argued that the existence of altruism in humans and other species is best explained by group selection.

Old Group Selection Versus Selfish Gene Theory: A History

Pre-1960s evolutionary biology frequently invoked group selection to explain what was thought to be the abundance of altruism observed in nature. This approach, now called “old group selection,” viewed natural selection as acting both between and within groups and presumed that between-group selection was often the dominant force. Old group selection was advanced by figures like Vero C. Wynne-Edwards and Konrad Lorenz, who regularly conceptualized evolution in terms of group benefit (Wynne-Edwards 1962; Lorenz 1966). Wynne-Edwards, for instance, believed that nature contained numerous “...collective attributes, all possessing the common quality of contributing to the welfare and survival of the group... and when necessary subordinating the interests of the individual” (Wynne-Edwards 1962 p. 653).

For example, biologists noted that animals fighting over mates or territory often engaged in ritualized aggression rather than “total warfare.” Because ritualized aggression was less costly than total warfare, it was thought that such behavior

had evolved through group selection (Lorenz 1966). Similarly, certain species were thought to rear fewer children than they were otherwise capable of. Again, biologists invoked group selection to explain such behavior (Wynne-Edwards 1962). Presumably, groups which exercised reproductive restraint were more likely to sustain their limited pool of resources. Those which failed to exercise such restraint would become overpopulated, and deplete their resources. Group selection was thought to explain other “collective attributes” as well, including territoriality and social orderings.

Old group selectionism was superseded by selfish gene theory from the 1960s through the 1980s due in part to two key theoretical developments – kinship altruism and evolutionary game theory – in conjunction with supporting empirical observation (Williams 1966; Dawkins 1976). According to selfish gene theory, the gene – not the group – is the fundamental unit on which natural selection acts. Although not entailed by selfish gene theory, selfish gene theorists tended view group selection as empirically implausible. While group selection was possible in principle, they argued, in practice within-group selection pressures would dominate between-group selection pressures.

In supplanting old group selectionism as the ascendant paradigm in evolutionary biology, selfish gene theorists were tasked with explaining – or explaining away – numerous ostensible examples of group-beneficial adaptations. Proponents of selfish gene theory noted firstly that much of what was thought to be altruistic behavior was in fact selfish. One notable example is that of the stotting gazelle. A group-selectionist explanation of this behavior might claim that healthy gazelles stot to draw the attention of predators to themselves and away from weaker members of the group. However, stotting could also be explained by selfish gene theory according to the “handicap principle,” in which a stotting gazelle purposefully handicaps itself to signal its fitness and agility both to mates and predators (Zahavi and Zahavi 1999). Other instances of ostensible altruism were explicable as exploitation, a now-famous example being that of enslaved ants (Franks and Scovell 1983). Upon closer

inspection, selfish gene theory argued, there was much less altruism to explain than group selectionists believed.

Moreover, two theoretical developments – kin selection and evolutionary game theory – allowed selfish gene theorists to explain the existence of cooperation and limited forms of altruism as the result of individual selection. Between 1963 and 1964, W. D. Hamilton punished a series of seminal papers expounding the notions of inclusive fitness, kin selection, and kinship altruism (Hamilton 1963, 1964). His central insight was that close relatives are more likely to share a rare allele than two randomly selected members of the population. If such a rare gene were to cause its bearer to exhibit altruism toward a close relative, it would stand a good chance of benefitting a copy of itself housed in that relative. An organism’s genetic success, Hamilton argued, was not merely the number of direct offspring it produced (personal fitness) but the number of direct offspring it produced summed with the number of direct offspring produced by its relatives, discounted by how distantly related they are. This latter measure would become known as *inclusive fitness*. Kinship altruism, Hamilton showed, will be selected for when an organism can decrease its personal fitness to increase its inclusive fitness (Hamilton 1964).

The second theoretical development which shifted evolutionary biology away from old group selection was evolutionary game theory. Under certain conditions, evolutionary game theorists demonstrated, cooperation between two organisms can be mutually fitness-enhancing. For example, it might pay for two organisms to engage in a series of quid pro quo transactions in which one individual cooperates with another under the expectation that cooperation will be reciprocated (Trivers 1971). Such an engagement is known as *direct reciprocity*. More generally, evolutionary game theory provided analyses of how ostensibly altruistic behavior was in fact mutually beneficial cooperation.

In 1973, John Maynard Smith and George R. Price applied a game-theoretical analysis to ritualized aggression, formerly thought to be an example of a group-level adaptation, and

demonstrated how such behavior could be mutually beneficial (Smith and Price 1973). The stage game they employed is called the *hawk-dove game*, in which two organisms or “players” compete for a common resource through one of two strategies: the aggressive strategy (hawk) or the nonaggressive strategy (dove). If both players choose hawk, they will each receive half the value of the resource $V/2$ but, in doing so, incur a cost from fighting $C/2$. When one player chooses hawk and the other chooses dove, the dove retreats leaving the hawk to claim the full value of the resource V . Finally, when two doves encounter one another, they will engage in minimally costly ritualized aggression before splitting the resources evenly for a payoff of $V/2$. The hawk-dove game can be represented in the following symmetric payoff matrix (each cell contains the payoffs for player 1):

		Player 2	
		Hawk	Dove
Player 1	Hawk	$\frac{V-C}{2}$	V
	Dove	0	$\frac{V}{2}$

Note that if the cost C of total warfare (hawk/hawk) is greater than the value of the resource V , the best response to hawk is dove. In a population of hawks, a single dove would enjoy an adaptive advantage. Because payoffs in evolutionary games represent fitness differentials, successive generations would see an increase in the relative frequency of doves and a decrease in the relative frequency of hawks. The composition of the population would converge to the mixed strategy Nash equilibrium, such that the expected payoff from playing hawk was equal to the expected payoff from playing dove. At this equilibrium, dove-dove ritualized aggression would be a common occurrence. The conclusion of this analysis, contra Lorenz 1966, is that ritualized aggression is not altruistic and does not require group selection to explain.

The introduction of dynamic or iterated games into evolutionary game theory demonstrated how repeated interactions create selection pressures for cooperation above what can be explained by static or one-off games (Axelrod 1984; Smith 1982).

A classic example of the potential for cooperation in dynamic games is the iterated prisoner’s dilemma. In the prisoner’s dilemma stage game, players choose one of two plays: cooperate or defect. If both cooperate, they receive a reward valued at R . If one cooperates and the other defects, the cooperator receives the sucker payoff S , while the defector receives temptation payoff T . If both players defect, they each receive punishment P . The values of these payoffs are given by $T > R > P > S$. According to this payoff structure, each player is Tempted to defect and take advantage of a cooperative Sucker, but if both players succumb to this temptation, they will be Punished rather than Rewarded. The cells of the following symmetric payoff matrix represent the payoffs for player 1:

		Player 2	
		Cooperate	Defect
Player 1	Cooperate	R	S
	Defect	T	P

In the static version of the prisoner’s dilemma, the unique Nash equilibrium is mutual defection. However, in dynamic or iterated versions, a new set of equilibrium strategies and payoffs emerge. Many of the subgame perfect Nash equilibria associated with the indefinitely iterated prisoner’s dilemma involve players electing to cooperate with positive probability. For instance, a strategy known as *tit for tat* (TFT) begins by cooperating and thereafter mimics its partner’s last play. Two TFT players will enjoy the reward payoff for the duration of the game. Furthermore, TFT is difficult to exploit, as it immediately punishes defection by defecting itself in the next round. These two characteristics of TFT (its ability to enjoy the benefits of mutual cooperation while remaining largely impervious to exploitation) explain its success in evolutionary simulations (Axelrod 1984). Several cooperative behaviors observed in nature can be modeled according to the iterated prisoner’s dilemma, such as when two individuals take turns grooming one another or sharing food (Dawkins 1976).

To summarize, the key point of departure between selfish gene theory and group

selectionism is that selfish gene theorists view between-group selection as a weak evolutionary force which is dominated by within-group selection, whereas group selectionists believe the opposite. In making their case, selfish gene theorists argue firstly that there is much less altruism to be explained than group selectionists believe and secondly that the few confirmed examples of genuine altruism can be accounted for by inclusive fitness theory and evolutionary game theory. By the 1970s, selfish gene theory had overtaken group selection as the dominant paradigm within evolutionary biology.

New Group Selection and Multilevel Selection Theory

Old group selection was modified and updated by several biologists and evolutionary theorists beginning in the 1970s, the work of whom would eventually culminate in a new group selection theory. While continuous with old group selection, new group selection improved upon its predecessor in at least two key respects. First, new group selection theorists provided mathematical analyses to identify the conditions under which between-group selection will dominate within-group selection. Second, new group selectionists extended the bi-level theory of old group selectionism to multiple levels of a biological hierarchy – a framework known as *multilevel selection* (MLS). Together, these modifications have contributed to group selection’s revival in modern evolutionary biology.

Formalizing Group Selection

To clarify the conditions under which between-group selection dominates within-group selection, new group selectionists divide fitness into “local fitness” and “global fitness” (Sober and Wilson 1998). Local fitness refers to the fitness of an individual relative to its group, while global fitness refers to the fitness of an individual relative to its population. When new group selectionists say that altruism will evolve when the group benefit outweighs the individual cost, they mean that altruism will evolve when the increase in global

fitness, averaged across individual members of the donor's group, is greater than the decrease in local fitness incurred by the donor. According to this framing, altruists simultaneously incur a cost in terms of local fitness while gaining a benefit in terms of global fitness. Consequently, the altruistic trait will decrease in frequency within the group but increase in frequency within the population (Wilson 1975a).

The causal hypothesis identified by group selection – that intergroup competition is a selection pressure for intragroup cooperation – lends itself to various mathematical formalizations. One notable formalization utilizes the Price equation, which models the changing frequency of traits over successive generations, to decompose the effects of between-group selection from those of within-group selection (Price 1970). According to the Price equation, altruism will be favored when there is high intergroup heterogeneity and intragroup homogeneity, that is, when altruists cluster in groups with other altruists. In this way, the altruistic trait will benefit from high levels of mutual cooperation while ensuring the same benefits are not reaped by selfish free riders.

For example, consider a group with n individuals. The rate of altruism within this group is r . Altruists act in such a way that confers a benefit of b to the group (b/n per individual) at a cost of c to themselves. For simplicity, suppose the outgroup population is composed of a large number of selfish individuals with a base rate fitness of x . The fitness of altruists (A) in such a group and the fitness of average group members (avg) are given as:

$$w(A) = x + rb - c$$

$$w(\text{avg}_{\text{group}}) = x + rb - rc$$

There are three important points to note in these equations (Sober and Wilson 1998). First, the fitness of altruists exceeds the population base rate if $rb > c$. When this occurs, the altruistic trait will increase in frequency within the population. Second, the fitness of altruists never exceeds the group average. When $r = 1$, the group is

composed entirely of altruists, in which case the within-group rate of altruism is intergenerationally stable. However, in the more realistic scenario when $r < 1$, the local fitness of altruists will decline. Together, these two points demonstrate the mathematical possibility of altruism evolving due to global fitness enhancements despite being locally costly.

Third, because of local fitness costs, the rate of altruism within this group will erode over successive generations. As the erosion becomes more severe, the group will reach a point where the fitness of altruists no longer exceeds the population base rate ($rb > c$ will no longer hold). Several mechanisms have been proposed to avoid the erosion problem, most notably preferential assortment (Grafen 1984) and group fission (Traulsen and Nowak 2006). In the case of preferential assortment, altruists selectively interact with other altruists and avoid cooperating with selfish individuals. In the case of group fission, groups are assumed to split once they reach a given capacity. After fissioning, the subgroups will compete with one another, allowing the more cooperative subgroup to outcompete the less cooperative subgroup. Fissioning models have been shown to maintain high levels of altruism under certain parameter values, even when intergroup migration is permitted (Traulsen and Nowak 2006).

Multilevel Selection Theory

In addition to mathematically modeling the causal process of group selection, new group selection theorists extended the bi-level theory of old group selectionism (between-group and within-group levels of selection) to multiple levels of a biological hierarchy (Wilson and Sober 1994; Okasha 2006). This extension is known as *multilevel selection* (MLS) *theory*. According to MLS, altruism at lower levels of the biological hierarchy evolves through competition at higher levels. For example, altruism at the genetic level can evolve through competition at the cellular level; altruism at the cellular level can evolve through competition at the individual level; and altruism at the individual level can evolve through competition at the group level. Rather than a rare and

exceptional evolutionary phenomenon, MLS maintains that the causal process underlying group selection is ubiquitous in evolutionary transitions.

A core concept of MLS is that selection can act on both replicators and vehicles. A vehicle, in this context, is an entity created by multiple replicators to enhance their reproductive success. Typically, these vehicles house the replicators which create them, thereby binding their reproductive fates. For instance, cells, multicellular organisms, and groups are all vehicles for genes. The biological hierarchy posited by MLS is composed of a series of nested vehicles, whereby genes are nested in chromosomes, which are nested in cells, and so forth. MLS argues that it is possible to speak about selection operating at every level of this biological hierarchy so long as it is clear that the fitness of these vehicles is determined by their ability to enhance the reproductive success of the replicators which created them (Sober and Wilson 1998).

Selfish gene theorists have argued against MLS, claiming that the application of natural selection at the group level is overreaching (Dawkins 1976). While selfish gene theorists acknowledge that selection can operate on the level of certain vehicles, such as multicellular organisms, they maintain that groups are not the right sort of vehicle on which natural selection can act. Multilevel selection theorists counter that there is no principled reason for the conclusion that selection can act on individual's *qua vehicle* but not group's *qua vehicle* (Sober and Wilson 1998).

Both formalized models of group selection and multilevel selection theory contributed to group selection's revival beginning in the 1970s. Even though these developments put group selection on firmer theoretical ground, new group selectionists still had to contend with the objection that the best explanations for altruistic behavior were kin selection and evolutionary game theory. If the existence of altruism could be explained in terms of individual selection, then invoking higher levels of selection would seem unparsimonious (Smith 1982).

New group selectionists responded by claiming that kin selection and game-theoretical

explanations of altruism were not, alternatives to group selection, but were rather equivalent frameworks describing the same underlying causal process. The concept of equivalence is discussed in the following section.

The Equivalence of Group Selection, Kin Selection, and Evolutionary Game Theory

Kin Selection

Despite the fact that kin selection was originally conceived of as an individual-level explanation for the evolution of altruism (Smith 1964), new group selectionists argue that kin selection is a specific instance of group selection for a group composed of close relatives (Wilson 1975a). According to the Price equation, what matters for the selection of altruism is not relatedness per se but rather a high covariance of altruistic traits within groups (Price 1970). Under this interpretation, kin selection is a type of group selection in which an altruistic trait achieves high intragroup covariance through common ancestry (Wilson 1975a; Grafen 1984). This interpretation of kin selection was subsequently adopted by W. D. Hamilton, who first formalized the conditions under which kinship altruism will evolve (Hamilton 1975).

To see how this works, consider a group composed of n relatives, each of whom is related to one another with an index of relatedness r . Now suppose some of these individuals contain allele A for kinship altruism which causes them to confer some benefit b to the group (per organism benefit b/n) at a cost of c to themselves. If A is rare within the general population, the number of altruistic individuals in the group is $r * n$. The respective payoffs for altruistic individuals and average members of the group are given by:

$$w(A) = x + rb - c$$

$$w(\text{avg}_{\text{group}}) = x + rb - rc$$

where x is the base rate payoff for members of the general population.

Note that these equations are identical to those in Formalizing Group Selection, and describe the same causal process by which altruism will experience positive selection. Namely, kinship altruism will increase within the population when $rb > c$ (Hamilton 1964). Moreover, altruists incur a cost in terms of local fitness, further supporting the contention that kin selection is an instance of group selection.

Evolutionary Game Theory

New group selectionists further contend that certain applications of evolutionary game theory also constitute group selection. Notably, it has been suggested that game-theoretical models of direct reciprocity which utilize iterated prisoner's dilemmas are specific instances of group selection with a group of size 2 (Sober and Wilson 1998). According to new group selection theory, the iterated prisoner's dilemma exemplifies a situation in which direct reciprocity evolves as a consequence of altruists incurring a cost in terms of local fitness while benefitting the group in terms of global fitness.

The intuitive explanation behind direct reciprocity parallels that of group selection. Within a mixed pair, selfish players beat cooperative players, but pairs of cooperative players outcompete pairs of selfish players. Between-pair competition favors altruism over selfishness – a miniature version of group selection.

The mathematical equivalence of new group selection, kin selection, and direct reciprocity has been used to argue that group selection is not an alternative mechanism by which altruism and cooperation evolve. Rather, group selection is a more general description of the causal mechanisms responsible for the evolution of altruism, which unifies kin selection and evolutionary game theory, and extends their logic to explain altruism in groups of varying sizes and degrees of relatedness (Sober and Wilson 1998). While group selection, kin selection, and evolutionary game theory are equivalent in their population dynamic predictions, new group selectionists contend that their theory offers certain conceptual advantages. For instance, group selection provides a useful lens through which to view the evolution of

altruism under complex conditions, such as cultural group selection and selection between multiple locally stable equilibria.

The Imprint of Group Selection on Human Psychology

One of the basic tenets of evolutionary psychology is that social behavior, including human social behavior, has its roots in biology. Therefore, any complete explanation of human social psychology must include the ultimate mechanisms by which sociality evolves (Wilson 1975b; Wilson and Wilson 2007). Kin selection, for instance, largely accounts for the psychology of nepotism, while moral emotions such as a sense of fairness can be explained as a logical consequence of direct reciprocity (Haidt 2012). If group selection played an important role in the evolution of *Homo sapiens*, its influence should be reflected in features of human social behavior. Indeed, a growing body of research from several fields, including psychology, behavioral economics, and anthropology, argues that it is (Fehr and Gächter 2002; Gintis et al. 2003; Haidt 2012; Greene 2014). There are at least two broad categories of evidence for group selection's influence on human psychology: altruistic punishment as an explanation of human ultrasociality and “groupish” psychological tendencies.

Altruistic Punishment as an Explanation of Human Ultrasociality

A unique feature of human behavior is our ability to cooperate in large, unrelated groups, often in one-off interactions where the potential for reputational gains is slight or nonexistent. This is known as *ultrasociality*. Human ultrasociality, it has been suggested, cannot be accounted for by the usual mechanisms postulated to explain cooperation: kin selection, direct reciprocity, indirect reciprocity, and network effects (Fehr and Gächter 2002). One mechanism to enforce ultrasocial levels of cooperation is altruistic punishment, whereby certain individuals pay a price to punish those who violate social or moral norms. If punishment is severe enough, this changes the

incentive structure facing group members, making it beneficial *at the within-group level* to engage in cooperative behaviors which, absent the threat of punishment, would be detrimental at the within-group level. Simply put, altruistic punishment makes otherwise altruistic behaviors selfish (Sober and Wilson 1998). Simultaneously, altruistic punishers experience a depreciation of local fitness, implying that punishing behavior is explicable only in light of group selection (Fehr and Fischbacher 2003).

Altruistic punishment in the context of group selection can be illustrated using a public goods game with punishment (Fehr and Fischbacher 2003). In the standard public goods game, n participants are given an endowment and offered the opportunity to contribute a portion of it to the “public good,” real-world analogues of which include government budgets, public services, the environment, and collective knowledge. The value of the public good is then multiplied by a factor m between 1 and n and distributed evenly among the participants irrespective of their contribution. Because the public goods multiplier falls strictly between 1 and n , contributing to the public good is an example of altruistic behavior, as the returns to contribution are m/n . In the original setup of the public goods game, a contribution of 0 is the dominant strategy, which should be unanimously adopted if all players are performing optimally. This game-theoretical prediction has been borne out in laboratory experiments, which show that participants in a public goods game decrease their level of contribution over successive iterations towards the unique Nash equilibrium (Fehr and Gächter 2002).

Variations of the public goods game which incorporate an element of punishment yield different results both theoretically and behaviorally (Fehr and Gächter 2002). In these variations, players are given the option to pay to punish one another after each round. If every player was reluctant to punish non-contributors, it would be in the interests of a single player to unilaterally deviate by choosing to punish those who failed to contribute to the public good. Severe punishment then acts as an enforcement mechanism. Players can expect to secure a higher payoff by

contributing to the public good and avoiding punishment than by failing to contribute and receiving punishment. In sum, what would have been altruistic behavior in the public goods game *without* punishment is selfish behavior in the public goods game *with* punishment.

Laboratory experiments which test the public goods game with punishment behaviorally find that human participants engage in altruistic punishment even when the element of repeated interactions is absent (Gintis et al. 2003). Because participants are willing to punish in one-off interactions, their behavior cannot be explained as a payoff-maximizing response to the game’s structure. Some behavioral economists suggest that a sense of fairness and inequity aversion are the proximate psychological mechanisms responsible for altruistic punishment (Fehr and Fischbacher 2003). These proximate psychological mechanisms, in turn, are indicative of group selection’s influence in shaping human psychology. While altruistic punishment is detrimental at the within-group level, it is beneficial at the between-group level, as groups with higher degrees of altruistic punishment exhibit greater intragroup cooperation and are therefore more successful in intergroup competition.

Groupish Psychological Tendencies

A number of moral and social psychologists have invoked group selection to explain the “groupish” characteristics of human psychology. In the same way that selfishness is the tendency to exhibit preferential treatment toward oneself over others, groupishness is the tendency to exhibit preferential treatment toward one’s own group over other groups (Haidt 2012). Such preferential treatment extends both to the individual members of one’s group and to the cultural norms of one’s group.

For example, anthropological surveys have identified norms of egalitarianism as a cultural universal (Brown 1991). Egalitarian norms, however, only hold insofar as they benefit the group. In general, equality within the group is considered less important than ensuring the group’s collective welfare (Henrich et al. 2004). Similarly, psychological research reveals that moral norms – particularly those relating to care, fairness, and liberty –

apply more strongly to ingroup members than to outgroup members (Greene 2014). Other types of moral norms – specifically those related to loyalty and respect for authority – arguably evolved to ensure group cohesion. Two prominent moral psychologists, Joshua Greene and Jonathan Haidt, suggest that the main evolutionary function of morality is to bind individuals together into a single group (Greene 2014; Haidt 2012).

Other demonstrations of ingroup bias come from the field of social identity theory (Tajfel et al. 1971). According to this theory, humans tend to identify as members of certain social groups on the basis of shared characteristics. Once these groups are established, individuals display ingroup favoritism (or intergroup discrimination), for instance, allocating larger rewards to ingroup members relative to outgroup members (Tajfel et al. 1971). Ingroup favoritism has been demonstrated experimentally even when groups are randomly assigned on the basis of arbitrary criteria, suggesting that ingroup favoritism can function as a cognitive bias (Tajfel 1970).

In addition to preferences for members of their group, psychological and anthropological research suggests that humans universally prefer over the norms of other groups (Richerson and Boyd 2005). While group selection hypotheses might explain partiality toward the *members* of one's group, it is less obvious why partiality toward the *norms* of one's group would have evolved. To explain this aspect of groupishness, some evolutionary theorists have invoked cultural group selection and gene-culture coevolution (Richerson and Boyd 2005). If group membership is contingent upon adherence to group norms, natural selection will favor individuals who are capable of adhering to the norms of their group. Successful groups, in turn, outcompete less successful groups, which increases the frequency of their norms within the population (cultural group selection). In effect, natural selection favors certain cultural norms via group selection, while cultural selection pressures favor individuals capable of adhering to the norms of their society. Once individuals have acquired the norms of their ingroup, they will tend to prefer them over the norms of the outgroup.

Criticism

Despite its decline in popularity in the late 1960s to early 1970s, group selection has experienced a revival in recent decades and is now one of the more contentious topics in modern evolutionary theory. Of the contemporary criticisms, at least three have emerged as the most common and substantive arguments against group selection. First, the language of new group selection is often seen as terminologically confusing, imbibing standard terminology with nonstandard definitions. Second, some theorists view equivalence as an argument *against* group selection, wondering why one would prefer a group selectionist account over, say, a kin selectionist account if they are ultimately equivalent theories. Finally, critics since John Maynard Smith have argued that new group selection suffers from anisomorphisms with respect to individual or gene selection and therefore should not properly be considered “group selection.”

New group selectionists see themselves as having updated the terminology of old group selection so as to clarify its underlying concepts (Sober and Wilson 1998). Critics, however, argue that new group selectionists are not merely “updating” their lexicon but are rather employing idiosyncratic redefinitions to standard terminology (West et al. 2007). For example, new group selectionists use “individual selection” to refer to selection for traits which enhance the fitness of individuals within their group, whereas “individual selection” traditionally refers to selection for traits which increase personal fitness (as opposed to inclusive fitness). Similarly, “altruism” is standardly used in reference to traits which decrease the personal fitness of their bearer in order to increase the personal fitness of another organism. Hence, kinship *altruism* evolves if individuals can increase their inclusive fitness by paying a price (in terms of personal fitness) to benefit a close relative. New group selectionists, however, call traits “altruistic” when they decrease the fitness of their bearer relative the group. Ultimately, these critics conjecture, much of the debate over group selection is attributable to

terminological confusion for which new group selectionists are at fault (West et al. 2007).

Another common argument against group selection runs as follows: New group selectionists contend that inclusive fitness theory, evolutionary game theory, and group selection are equivalent. Indeed, mathematical formalizations of group selection yield identical population dynamic predictions to those of inclusive fitness theory and evolutionary game theory. However, if these mechanisms are indeed equivalent, then what novel contributions does group selection make to evolutionary theory (West et al. 2007)? According to this line of reasoning, group selection collapses into a redescription of the previously established selection mechanisms. New group selectionists have responded by noting that, while group selection is equivalent to kin selection and evolutionary game theory in certain respects, group selection may offer certain conceptual advantages (Wilson 2015). For instance, group selection provides a useful lens through which to view the evolution of altruism under complex conditions, such as cultural group selection and selection between multiple locally stable equilibria.

Perhaps the deepest conceptual issue surrounding the group selection debate regards the anisomorphism between group selection and other levels of selection, such as selection at genetic or individual level. Specifically, certain critics (most notably John Maynard Smith) have argued that group selection fails to provide a convincing account of how group-level adaptations are inherited (Smith 1987). Whereas, in individual selection, parent organisms spawn characteristically similar offspring organisms, group selection does not involve parent groups spawning characteristically similar offspring groups. While Maynard Smith concedes that intergroup competition may select for intragroup cooperation (and other intragroup traits), he argues that this is insufficient to establish group selection. Because such traits are inherited through individual (rather than group) reproduction, they are best viewed as arising from individual (rather than group) selection (Okasha 2006).

Conclusion

Group selection is the hypothesis that natural selection acts at the group level, favoring certain group-level characteristics over others. According to group selection theorists, natural selection acts both between groups in a multigroup population and between individuals within a group. Within-group and between-group selection are opposing forces, with selection among individuals within a group favoring selfishness and selection among groups within a multigroup population favoring altruism. Old group selectionists believed that selection between groups would typically dominate selection within groups, resulting in adaptations “for the good of the group.” This paradigm was replaced by selfish gene theory in the 1960–1980s due to both theoretical and empirical developments in evolutionary biology. Most notably, kin selection and evolutionary game theory purported to explain how cooperation could arise from individual selection, obviating the explanatory necessity of group selection.

In the 1970s, several evolutionary theorists began revising and updating old group selection in at least two key respects. First, new group selection theorists provided mathematical analyses to identify the conditions under which between-group selection will dominate within-group selection. Second, new group selectionists extended the bi-level theory of old group selectionism to multiple levels of a biological hierarchy, resulting in the framework of multilevel selection (MLS). Although group selection is a causal hypothesis – not a formalism – mathematical analysis helped put group selection on firmer theoretical footing. Moreover, analogizing group selection to other evolutionary transitions using the MLS framework lent credibility to new group selection theory.

One notable result of new group selectionists’ mathematical analyses is that the population dynamic predictions of group selection theory are identical to those of inclusive fitness theory and evolutionary game theory. In this sense, group selection, kin selection, and non-zero sum evolutionary games can be viewed as equivalent mechanisms underlying the evolution of cooperation

and altruism. To the extent that these mechanisms are not equivalent, some evolutionary theorists (e.g., David Sloan Wilson) have argued that group selection offers certain conceptual advantages, such as the ability to understand the evolution of altruism under complex conditions.

A growing body of research from several fields, including psychology, anthropology, and behavioral economics, claims to have found evidence of group selection's imprint on human social behavior. First, several behavioral economists have argued that altruistic punishment, in which the altruistic punisher incurs a personal cost to punish those who violate social or moral norms, is a mechanism for ensuring ultrasociality. Because the administration of punishment is individually costly, group selection may explain why altruistic punishment evolved. Second, social psychology and anthropology have uncovered a number of "groupish" psychological tendencies, in which humans favor the members and norms of their own group over those of other groups. The prevalence and universality of ingroup favoritism is often seen as further evidence for group selection's influence on human psychology.

Group selection theory continues to be the subject of numerous criticisms. Opponents of group selection theory argue that group selectionists utilize idiosyncratic redefinitions of standard terminology and note that the concept of equivalence calls into question the explanatory utility of group selection. Perhaps the deepest conceptual criticism regards the anisomorphism between group selection and individual or gene selection, with detractors arguing that group selection theory fails to provide a convincing account of group heritability. Ultimately, these and other issues surrounding group selection contribute to its status as one of the more controversial topics in modern evolutionary theory.

Colony size; The size of a group

Definition

The total number of individuals comprising in a social group.

Introduction

Animal groups vary greatly in size. Male wild turkeys form coalitions of two to four members to attract females. Cliff swallows breed in colonies ranging from a few pairs to thousands of individuals. Antarctic krill aggregate in dense swarms, which number up to a trillion individuals and can be visible from space. As these examples illustrate, not only does group size differ between species but it can also highly differ within species

(Krause and Ruxton 2002; Ward and Webster 2016).

What determines group size? How are animal group sizes distributed? Adaptive explanations for social grouping posit that there are a wide variety of fitness costs and benefits associated with group membership and that each individual would prefer the optimal group size, i.e., the size that maximizes his/her own inclusive fitness (Pulliam and Caraco 1984). This entry explores how natural selection will act to shape the optimal group size and why there is such a variation in the distribution of actual group sizes.

Optimal Group Size

Living in a group entails both costs and benefits. Potential benefits of group living include predator avoidance (e.g., group defense, improved vigilance, dilution of predation risk), increased foraging success (e.g., information sharing, group hunting), aerodynamic or hydrodynamic advantages in locomotion, protection from climatic extremes (e.g., huddling for warmth), cooperative territorial defense, and increased probability of winning intergroup competition. Group membership, however, may impose costs such as intragroup competition for resources, increased attack rate on larger groups, disease transmission, brood parasitism, and cuckoldry (Alexander 1974; Krause and Ruxton 2002; Wilson 1975).

Clearly, the costs and benefits of group living will vary systematically with group size. In most cases, as group size increases, the benefits to each group member would increase with diminishing returns (a newly added individual has less impact than the last). By contrast, the costs to each member would increase with increasing returns (a newly added individual has more impact than the last). As groups become very large, the costs of grouping will eventually always exceed the benefits. Under those conditions, the fitness function will reach a maximum at an intermediate group size, i.e., the optimal group size, and decrease thereafter. Natural selection should have favored individuals that form groups of

optimal size (Caraco and Wolf 1975; Pulliam and Caraco 1984; Rodman 1981; Wilson 1975). Note that the fitness function with an intermediate optimal group size may not always hold. In some situations, grouping may be always disadvantageous and individuals will be selected to be solitary.

The optimal group size model rested on several simplistic assumptions; subsequent models relaxing the assumptions were developed, as discussed below:

The Rules of Entry into Groups

The aforementioned model tacitly assumes that existing group members have full control over a newcomer's entry into the group: they would recruit solitary outsiders when the group size is below the optimum, n_I , or prevent solitaries from joining the group when the group size is at the optimum, n_I (Fig. 1). Under this group-controlled entry, the maximal benefit of group living can be attained (Caraco and Wolf 1975; Rodman 1981; Wilson 1975). However, things change when a solitary outsider is assumed to exert full control over her own entry into a group: a series of solitary individuals arrive sequentially and each would freely decide whether to join the group or to remain alone. Under the free entry, solitary outsiders are expected to enter the group as long as the fitness of a group member exceeds that of a solitary outsider. Group size continues to increase up to a certain size, n_O , at which joining the group no longer increases a solitary outsider's fitness (Fig. 1) (Clark and Mangel 1984; Sibly 1983).

Therefore, the group size favored by a group insider, n_I , is less than the group size favored by a solitary outsider, n_O . It means that there is a potential genetic conflict of interest between insiders and outsiders over group size. Within the zone of conflict between n_I and n_O , a solitary outsider "wants" to enter the group, whereas a group insider "wants" the outsider to remain outside (Giraldeau and Caraco 1993; Higashi and Yamamura 1993). It is worth mentioning that models identifying the potential for insider-outsider conflict over group size do not themselves make testable predictions about what group size should be predominantly observed in

nature (Godfray 1999). For such predictions, a different class of models are needed that seek to predict how the potential genetic conflict is resolved at the level of phenotypic interactions between group insiders and a solitary outsider (Cant 2011; Higashi and Yamamura 1993; Port et al. 2011).

Effect of Genetic Relatedness

Initial models of optimal group size were based on regular (direct) fitness, i.e., the number of progeny an individual produces over lifetime. They thus treated group-forming individuals as if they were unrelated. As many instances of animal groups are actually composed of genetic relatives, later models took into account the effect of genetic relatedness on the size of groups (Giraldeau and Caraco 1993; Higashi and Yamamura 1993).

Under the group-controlled entry, an insider living in a kin group of the “optimal” size, n_I , will still tolerate the joining of a related outsider to the group, as long as the indirect benefit to the outsider outweighs the direct cost to the insider herself. That is, the inclusive fitness (IF)-based group size favored by an insider, n_I^* , is equal to

or larger than the regular fitness (RF)-based group size favored by an insider, n_I (Fig. 1). Further, increasing relatedness may ordinarily increase, and will never decrease, the IF-based group size favored by an insider, n_I^* .

Under the free entry, a related outsider may choose not to enter a kin group that has not yet reached the RF-based group size favored by an outsider, n_O , as long as the indirect benefit to the insider outweighs the direct cost to the outsider herself. That is, the IF-based group size favored by an outsider, n_O^* , is equal to or smaller than the RF-based group size favored by an outsider, n_O (Fig. 1). Moreover, increasing relatedness may ordinarily decrease, and will never increase, the IF-based group size favored by an outsider, n_O^* (Giraldeau and Caraco 1993, 2000; Higashi and Yamamura 1993).

Effect of Dominance Hierarchy

In reality, individuals in a group may differ in their competitive abilities. As a consequence, each group member may prefer different group sizes according to their relative ranks in the dominance hierarchy. Reeve and Emlen (2000) applied

Group Size, Fig. 1. The fitness, $w(n)$, of an individual in a group, where n is group size. The optimal group size from the viewpoint of a group insider, n_I , is less than the optimal group size from the viewpoint of a prospect joiner, n_O . Further, the inclusive fitness (IF)-based group size favored

by an insider, n_I^* , is equal to or larger than n_I . The IF-based group size favored by an outsider, n_O^* , is equal to or smaller than n_O .

reproductive skew theory to predict the size of a group in which a single dominant individual and multiple subordinates exist. They assumed that (1) expected group output is an increasing, but decelerating function of group size, (2) the dominant should yield just enough reproduction to each subordinate to induce them to stay in the group rather than to breed solitarily, and (3) the dominant has the ability to eject a subordinate from the group. Their model predicted that increasing relatedness would decrease the “optimal” group size from the viewpoint of the dominant individual. Interestingly, this prediction is in stark contrast with those of the “group-controlled entry” version of the earlier models, which predicted that increasing relatedness would generally increase the “optimal” group size from the viewpoint of group insiders (Giraldeau and Caraco 1993; Higashi and Yamamura 1993). The divergence occurs because, in Reeve and Emlen’s (2000) skew model, the dominant individual is more likely to eject a closely related subordinate from the group. By doing so, the single dominant member will gain greater indirect fitness benefits from the solitary output of the closer relative. In contrast, the earlier models not assuming the dominance hierarchy in social groups find that each and every group insider will gain indirect fitness benefits from the entry of a related outsider (Giraldeau and Caraco 1993; Higashi and Yamamura 1993).

Group Size Distributions Observed in Nature

How do theoretical predictions about the optimal group sizes compare with empirical observations of the actual group sizes? As shown above, theoretical models predict that group size distributions should have a single peak at the optimal group size and a very narrow variation around this maximum (Caraco et al. 1980; Clark and Mangel 1986). However, the variation in the observed group sizes for a number of animal species is usually much wider than predicted by these models. In such species as ungulates, fish, and social spiders, group size distributions are

highly right-skewed and long-tailed: while there are lots of small groups, a few exceptionally large groups do exist that are often several orders of magnitude larger than the modal group size (Avilés and Tufino 1998; Bonabeau and Dagorn 1995; Bonabeau et al. 1999; Gerard et al. 2002; Sumpter 2010). Such long-tailed distributions often follow a power law. For instance, plotting the logarithms of tuna school sizes against the logarithms of their frequencies, Bonabeau and Dagorn (1995) showed that the data in the log-log plot were fitted by a straight line with a slope of -1.5 , meaning that a group size n occurs with a frequency of $n^{-1.5}$.

Long-tailed distributions of group sizes in the wild have sparked the interests of many theoretical physicists. Instead of asking which group size an individual should be selected to prefer so as to maximize his/her inclusive fitness, researchers tried to find the simplest set of rules for the fission and fusion of social groups that can generate long-tailed group size distributions, including power law distributions (Bonabeau and Dagorn 1995; Sumpter 2010). Bonabeau and Dagorn (1995) developed a model of group formation based on an extremely simple assumption: when groups meet they always merge to form a larger group. Their model predicted a power law distribution of group sizes, which appeared somewhat consistent with the empirical data of fish schools. Bonabeau and Dagorn’s (1995) model, however, has been criticized for its biologically unrealistic assumption that the population should keep increasing to infinity with time in order to get a power law in group size distributions (Ma et al. 2011; Sumpter 2010).

Niwa (2003, 2004) proposed another model of animal aggregation and breakup. The model’s assumption about aggregation were identical to Bonabeau and Dagorn’s: when groups meet at any site they always merge. Yet Niwa further assumed that each group may split into two sister groups – the size of which is chosen uniformly at random. Niwa (2003, 2004) showed that, simply by measuring the expected group size experienced by a randomly chosen individual for a particular species, one can predict the whole distribution of group sizes in that species (Ma et al. 2011).

Moreover, the predicted long-tailed distributions of group sizes for six different fish species fitted well with the empirical data.

Note that the mechanistic approach seeking the simple rules of group fission and fusion that agree well with observed group size distributions is distinct from the functional approach seeking the optimal group size resulting from the balance between the costs and benefits of group membership (Sumpter 2010). In other words, although mechanistic models make implicit assumptions about the set of behavioral rules by which individuals join and leave groups, they fail to take into account how such rules could have affected the inclusive fitness of a group member over evolutionary history. Obviously, it would be desirable to investigate models of group fission and fusion in the context of optimizing group size (Krause and Ruxton 2002; Sumpter 2010).

Conclusion

The size of group in which animals live may reflect the optimal balance between the fitness costs and benefits of group living. From the viewpoint of each individual in and out of a group, however, the optimal group size is likely to differ between them according to whether (1) the individual is an existing group member or a prospective joiner, (2) the individual is genetically related to others, and (3) the individual occupies a dominant or subordinate position within the dominance hierarchy in the group. Consequently, there should be a potential genetic conflict of interest between individuals over the size of the group. Future studies should pay more attention to at what group size the conflict will be resolved. Ideally, such a resolution model should generate long-tailed distributions of group sizes, thereby accounting for the observed group-size distributions in the wild.

Optimal versus stable group size

Definition

The group size that maximizes the average fitness of group members; the group size which, if prevalent in a resident population, cannot be evolutionarily invaded by any slightly different group size.

Introduction

Adaptive explanations for group living have suggested that individuals choose to live in groups of

optimal size where the inclusive fitness of each group member is maximized (Caraco and Wolf 1975; Pulliam and Caraco 1984; Rodman 1981). Yet Sibly (1983) pointed out that the optimal group size may not be stable; the stable group size to be observed in nature will frequently exceed the optimum. This happens because a solitary outsider will do better by joining a group of optimal size rather than by remaining alone, even though the average fitness of group members is reduced by the addition of a newcomer (Clark and Mangel 1984; Sibly 1983). The size of a group is expected to increase until group insiders do not fare any better than solitary individuals, which seems paradoxical (Giraldeau 1988; Giraldeau and Caraco 2000). This entry examines whether the optimal group size is indeed unstable.

Is the “Optimal Group Size” Unstable?

As stated above, earlier models for the evolution of group formation have viewed that selection would favor individuals residing in groups of optimal size. Let $w(n)$ be the average fitness of group insiders within a group of n individuals. As n grows, the fitness function $w(n)$ is typically assumed to initially increase, to attain a maximum at an intermediate group size n_I , and to decrease afterward. It is further assumed that $w(n)$ drops below $w(1)$ once n goes beyond a certain value n_O (i.e., $w(n) \geq w(1)$ for $n \leq n_O$, while $w(n) < w(1)$ for $n > n_O$). Then n_I is the group size that maximizes $w(n)$ for its members, the “optimal group size” (Caraco and Wolf 1975; Pulliam and Caraco 1984).

Sibly (1983), however, contended that groups of optimal size may rarely be found in nature. The argument was based on his specific assumptions regarding how groups are formed: (1) a series of solitary outsiders arrives at a site singly, (2) each outsider has a choice between living alone and entering a group at no cost, and (3) group insiders leave a group individually. Under these circumstances, solitary outsiders will join a group of size n as long as the resulting fitness they would gain in that group size, $n + 1$, is larger than the fitness of being on their own (i.e.,

$w(n+1) > w(1)$). Note that solitaires will join the group even when their joining decreases the average fitness of group members (i.e., $w(n) > w(n+1)$). Group size continues to grow up to n_O , at which solitary outsiders no longer enter the group (i.e., $w(n+1) < w(1)$ when $n = n_O$) and no group insiders leave the group singly. Then n_O is called the “stable group size.” Accordingly, self-interested animals would cause the stable group size to be larger than the theoretically predicted optimum (Sibly 1983). Thus, a paradox arises where gregarious individuals end up in a group of stable size for which group membership bestows no benefit over living alone.

Stable from Whose Point of View?

In order to investigate whether the “optimal group size” is unstable, one should observe that Sibly’s (1983) model was constructed on his strict assumption that a solitary outsider has complete control over her own entrance into a group. As covered in the chapter entitled ▶ “Group Size” in this volume, different assumptions about who is in control over a newcomer’s entry can make markedly different predictions regarding group size. Under the assumption of free entry, the “optimal group size” n_I maximizing the average fitness of group insiders is certainly neither optimal nor “evolutionarily stable” from the viewpoint of a solitary outsider. As shown above, the optimal and evolutionarily stable group size for an outsider is the “stable group size” n_O . It is worth noting that evolutionary stability can be determined by verifying whether a resident population fixed for a particular strategy is resistant to the invasion of any mutant strategy (Otto and Day 2011).

Consider the opposite assumption that group insiders exert full control over a newcomer’s entry. Under the assumption of group-controlled entry, the “optimal group size” n_I is both the optimal and evolutionarily stable group size from the viewpoint of a group insider. As Sibly (1983) cogently argued, the “optimal group size” n_I for an insider is neither optimal nor evolutionarily stable for a solitary outsider. Hence,

the baffling conclusion of Sibly’s (1983) model largely arouse from semantic confusion over *from whose point of view* the “optimal group size” is evolutionarily stable. The “optimal group size” for a group insider is evolutionarily stable from the viewpoint of an insider; however, it is unstable from the viewpoint of an outsider.

Resolution Models Predict the Observed Group Size

Which group size could we expect to observe in the wild? Given that group insiders and solitary outsiders have different fitness optima concerning group size, so-called “resolution” models are needed that would predict how the evolutionary conflict between insiders and outsiders is likely to be resolved in behavioral terms (see the entry ▶ “Group Size” in this volume). The evolutionarily stable group size predicted by such a resolution model is what we actually should expect to see in natural populations. For instance, Higashi and Yamamura (1993) found that the resolution of the insider-outsider conflict over group size should eventually result in a “compromise groups size” that lies between the group size favored by an insider (the “optimal group size” n_I) and the group size favored by an outsider (the “stable group size” n_O). Seno (2006) constructed a resolution model of group size that takes into account the influences of fusion and fission within and between groups.

Viewed in this light, it can be seen that Sibly’s (1983) model has brought about some unfortunate difficulties in making general predictions about actual group size in nature. Undoubtedly, the free entry assumption will hold in some cases, such as the formation of sea birds’ breeding colonies or the formation of some animal species’ nocturnal roost sites, where existing group members have little chance to prevent a solitary outsider from joining them (Giraldeau and Caraco 2000). It seems reasonable, however, to suppose that in most situations neither insiders nor outsiders would have complete control over an outsider’s entry. Thus, the evolutionarily stable group size found in the wild is highly likely to represent

a compromise between the different fitness optima of insiders and outsiders. The mere fact that the observed group size of a particular animal species turned out to be larger than the theoretically “optimal group size” for an insider (e.g., Caraco and Wolf 1975) in no way demonstrates that the optimal and evolutionarily stable group sizes do not normally exist in natural populations.

Conclusion

Sibly (1983) argued that, since the optimal group size is unstable, the mean group size observed in nature will be generally larger than the optimum. Semantic confusion exists in the literature concerning from whose point of view the “optimal group size” is evolutionarily stable. The “optimal group size” for a group insider is certainly stable from the viewpoint of an insider, whereas it is unstable from the viewpoint of an outsider. It is so-called “resolution” models that do predict the mean group size that should be predominantly found in natural populations.

Introduction

The formation of groups is one of the most conspicuous and striking behaviors seen in animals. It is observed across a diverse range of living organisms, from colonies of multicell slime molds to human cities that rely on extensive and complex infrastructure. The reasons we may observe a set of individuals in closer proximity to one another than expected from a random distribution are varied. Animals that are usually asocial may

aggregate around a food resource, such as brown bears (*Ursus arctos*) feeding on migrating salmon in rivers, or aggregation may emerge simply from a lack of dispersal, where offspring tend to be found in close proximity to their parents and other relatives. In many other cases, however, aggregations are a result of *social attraction*, where individuals actively seek out the company of others. Once such groups form, they can be very stable, with the group moving as a unit, synchronizing their activity and behavior over space and time. This stability of group membership can then give rise to complex social behaviors such as dominance hierarchies and altruism.

The question of why animals actively form groups is a long standing question in animal behavioral research (e.g., Miller 1922). Competition for resources (e.g., food or breeding sites) often leads to aggression, and close proximity to others can have a significant negative impact on an individual's reproductive success. A number of mechanisms for why group living may be favored in evolutionary terms have been supported with theoretical, experimental, and observational studies: moving through space may be energetically less costly via hydro- and aerodynamic effects, and resources may be more easily found and/or exploited in groups (Ioannou 2017). The most common and widespread explanation for why animals live in groups, however, is because predation risk is reduced in groups (Rieucou et al. 2015).

The Social Response of Prey to Predation Pressure

Evidence that animal groups have evolved to reduce predation risk comes from studies demonstrating that social tendencies are greater with higher levels of predation. This trend exists at the short time scale of individuals detecting and responding to cues indicating higher predation risk. For example, using a carefully manipulated experimental design, Hoare et al. (2004) demonstrated an increased group size in the banded killifish (*Fundulus diaphanous*) when exposed to a nondirectional predator odor cue. An alternative

approach is to compare social behavior between populations found in low versus high predation habitats, where exposure to predation risk varies at a much longer time scale (i.e., generations compared to minutes or hours). Beauchamp (2004) demonstrated that populations of various bird species tended to form smaller flocks on islands compared to mainland populations, where predation risk is reduced in island habitats. Over a small geographical range but across multiple populations, Seghers (1974) similarly showed that populations of the guppy (*Poecilia reticulata*) in the Northern Range Mountains of Trinidad have a reduced shoaling tendency in habitats with fewer and less dangerous predators. Additionally, it was shown that these shoaling tendencies were heritable.

Mechanisms for the Reduction of Predation Risk in Groups

In addition to studies of how social tendencies vary with predation pressure, a number of mechanisms which drive the reduced risk in prey groups have been proposed and are supported from studies of behavioral predator-prey interactions. These mechanisms reduce the overall predation rate by reducing the chance the prey are detected or captured and/or, for each attack, shifting the risk to less aggregated individuals. Disentangling the mechanisms that reduce the risk of predation in groups can be problematic; although through careful experimentation, analysis of data, and knowledge of the biology of predators and prey, each of the mechanisms detailed here is well established in the literature. These antipredation grouping mechanisms are ordered from those requiring simple behaviors in the prey to those that are more advanced.

The Dilution Effect, Attack Abatement, and Detecting Groups of Prey

The simplest mechanism for reducing predation risk in groups is the dilution effect. As group size increases, the probability that any single

individual is selected for attack decreases, so that the per capita risk of predation is $1/n$, where n is the prey group size. Foster and Treherne (1981) were the first to provide strong evidence for this effect, by observing rates of predation on a marine insect, the ocean skater *Halobates robustus*. Due to the biology of the system (the prey cannot detect and respond to imminent attacks from below by the fish predator in the study, *Sardinops sagax*) and a close match between observed and expected risk at different group sizes, Foster and Treherne convincingly showed that the dilution effect could reduce risk in larger groups in a naturally occurring predator-prey system. They also showed that the dilution of risk between group members had a greater effect on risk than a reduced attack success in larger groups, possibly caused by the confusion effect (see below), suggesting that risk dilution is the dominant mechanism explaining group living in this species.

Although intuitive, further work refined the circumstances under which risk would be reduced due to a dilution effect. Turner and Pitcher (1986) argued that in addition to risk being diluted between group members, the number of attacks on groups would need to be less than proportional to the group's size ("attack abatement," also referred to as encounter-dilution). In other words, if a group twice as large is attacked twice as often, the dilution effect would be canceled out. While Foster and Treherne (1981) did show there was no relationship between group size and the rate of attacks per group, there are a number of reasons why larger groups may receive more attacks in other predator-prey systems. Larger groups are more conspicuous simply due to their increased size, although the relationship between group size and conspicuousness tends to be less than directly proportional (Treisman 1975), suggesting that attack rates are still lower in larger groups per individual prey. Recently, Ioannou et al. (2011) argued that rather than considering groups of different sizes, a more ecologically relevant question is how a population of prey should distribute themselves to minimize detection by predators, i.e., whether to form a single, large group, or to distribute themselves in smaller groups or as individuals. Using a combination of an

experiment and a simple model, Ioannou et al. (2011) found that while larger groups are more easily detected, the reduced encounter rate between predator and prey when there are fewer groups is a stronger effect, leading to an overall decline in the rate at which predators are expected to detect prey as group size increases. These studies, however, have used (Ioannou et al. 2011) or assumed (Treisman 1975) simple prey that do not change their behavior in larger groups. There may be greater per capita activity in larger groups, for example, through increased competition for food, and this may make larger groups disproportionately more conspicuous and hence preferentially targeted.

Once detected, there are other ways in which the number of attacks could increase with group size. Predators often attack and consume multiple prey per encounter, for example where predators can ingest numerous prey simultaneously, as with filter feeders (Rode et al. 2013), or when multiple predator individuals are simultaneously attacking a group. When foraging on cryptic prey that do not flee or show other evasive behaviors, predators often conduct "area restricted" searches once a first prey is found (Hill et al. 2003). When aggregated, this increases the foraging success of the predator, and increases risk to prey. In cases where multiple prey are consumed in each encounter, it may be advantageous for prey not to be social, and instead distributed themselves throughout the habitat (Treisman 1975). However, the time taken to handle and process each prey item will place a limit on the rate of consuming prey (Holling 1959), and this is likely to mean that attacking larger groups may provide little benefit for the predator relative to smaller groups if handling time restricts the rate of prey consumption. Thus, there may be a reduced incentive to attack larger groups, especially if other mechanisms, such as the confusion effect and group vigilance (see below), reduce the likelihood an attack is successful.

The Selfish Herd

A mechanism often discussed alongside the dilution effect is Hamilton's selfish herd effect (Hamilton 1971). As with the above mechanisms,

the selfish herd can explain group living simply through the spatial distribution of prey, without the prey needing to move, coordinate, or otherwise communicate with one another. The selfish herd model assumes that predators can appear anywhere in the environment and will attack the nearest prey. Thus, to avoid predation, prey should position themselves to be closer to other prey, selfishly reducing their “domain of danger” (the space closer to that individual than any other), and hence forming densely packed groups. Prey often show a short-term response of reducing interindividual distances upon detecting a predator (Hoare et al. 2004; Viscido and Wethey 2002), although this could be a response which increases the efficacy of confusion and group vigilance effects (see below), rather than solely to reduce domains of danger. Few studies have quantified domains of danger in prey groups and shown them to be directly proportional to the risk of mortality, or to what extent proximity to individual prey in groups affects a predator’s selection of which individual to target relative to other variables.

Confusion Effect

The confusion effect is a popular concept and is rarely omitted from the reasons why animals live in groups. Aggregation of prey results in more prey individuals within the visual field of a predator, which can overwhelm a predator’s cognitive ability to quickly select and successfully attack a target prey when many other possible targets are visible. This can reduce the rate of attacks made, make attacks less successful, and/or shift attacks to targets with fewer prey nearby, such as those on the periphery of the group or those that are separated from the group. The confusion effect can also explain the targeting of phenotypically odd individuals (the “oddity effect”), which stand out more against the background of their similar-looking group mates (Landeau and Terborgh 1986). This oddity effect can help account for assortment of phenotypes in groups, and synchronization of behavior, as behaviorally odd prey can also be preferentially targeted by predators. Evidence that targeting prey in groups is cognitively demanding includes experiments using three-

spined sticklebacks (*Gasterosteus aculeatus*) attacking groups of *Daphnia*, where detection rates of the sticklebacks’ own predator decreased when they were attacking a high, rather than low, density prey group (Milinski 1984).

Current evidence suggests that the high synchronization and coordination seen in some bird flocks and fish schools is not necessary to induce a confusion effect (Ruxton et al. 2007), although studies on a greater range of animals are needed to generalize this conclusion. Neural network models (Tosh and Ruxton 2010) have been used to explain how the confusion effect arises as an information-processing constraint of predators. Only group size and spatial arrangements of prey are used as the visual input into such models, with no interaction between prey or even any prey movement, suggesting that the confusion effect may be widespread in predators of aggregated prey. The effect is unlikely, however, to be important in predators which do not target individuals, such as flamingoes which filter feed (Rode et al. 2013).

Group Defense

Living in groups can allow collective defense of the group to stop predation by predators that may otherwise be too dangerous for a single individual to defend themselves (or their offspring) against alone. A classic example of group defense is the arrangement of adults around young in bison herds, where the wall of horns and muscle creates a formidable defense against attacking wolves. However, most studies of group defense come from birds, particularly from nesting colonies. Rates and effectiveness of mobbing potential predators typically increases with colony size (e.g., Hoogland and Sherman 1976), and experiments using artificial nests show predation is decreased when these are closer to larger, rather than smaller, colonies (Andersson and Wiklund 1978). As well as stopping successful attacks, mobbing can function to signal to a predator that they have been detected, which may deter attacks if the predator relies on surprise to be successful. The close proximity of prey to predators during mobbing also allows prey to learn about the level of threat an individual predator

poses, and can allow less experienced prey to learn about potential threats from more experienced individuals (Graw and Manser 2007).

Group Vigilance (the “Many-Eyes” Effect)

Vigilance for predators and other threats is common in prey animals. When in groups, the “many-eyes” looking out for danger mean that predators are more likely to be detected (Siegfried and Underhill 1975). If this information can transfer between individuals and through the group, it can significantly reduce the rate of successful attacks on groups if appropriate behavior is performed, such as fleeing or signaling to the predator that they have been detected. As well as a mechanism reducing risk in groups, this collective detection is an example of social information use, as it allows individual prey to respond to publically-available information (the response of near neighbors or intentional alarm signals) without all prey having to directly detect the threat (Herbert-Read et al. 2015).

Of the mechanisms that reduce predation risk in groups, group vigilance is the only one that relies on information transfer between individuals. Information transfer may be through intentional, active signals, such as alarm calls, or via unintentional cues such as the fleeing response of near neighbors. Collective detection also applies outside of a predator-prey context; for example, collective detection of food can show a similar pattern (many eyes are more likely to detect a food source, which is information then transferred through the group). Ward et al. (2008, 2012) elegantly showed that the same collective response rule (quorum decision making) could describe the collective detection of either a predator or a food source in a Y maze using three-spined sticklebacks (*G. aculeatus*). There is growing interest in the way that information (regarding possible threats or resources) flows between individuals in groups, and this has been greatly facilitated by recent technological advances where the movement of individuals in groups can be tracked in detail (e.g., Herbert-Read et al. 2015).

Vigilance is also important for studying aggregation in animals because it can indicate the level of risk perceived by individuals. Rates of vigilance typically decrease in larger groups (Roberts 1996), suggesting lower perceived risk, and this lower risk can be via any combination of the anti-predatory grouping mechanisms described above. It will, however, lessen the extent that collective detection improves detection of predators. Competition for food and other resources may also explain why vigilance decreases in larger groups, as individuals need to pay greater attention to finding food when competition is more intense.

Conclusion

Almost all animals face predation at some point in their lives, even if this is just in vulnerable juvenile life stages. Living in groups is a common strategy to mitigate the risk of predation and has evolved independently and repeatedly in numerous taxa. However, there are a number of limitations on our current understanding of grouping and predation. Most studies have considered visual detection only (both of prey by predators and vice versa), and relatively little is known about whether the conspicuousness of larger groups, the confusion effect, and group vigilance alter when other sensory modalities are used. Similarly, little is known about whether environmental variables, such as turbidity in aquatic habitats, have an effect on the mechanisms that make groups safer for prey. A challenging but worthwhile aim for future work would be to bring together the common antipredation grouping mechanisms under a single framework to determine and predict which combination of mechanisms would be favored under different conditions. For example, prey that cannot detect the first attack by a predator are unlikely to benefit from group vigilance, but may benefit from a confusion effect if they are moving before the attack occurs (Foster and Treherne 1981).

There also remains a bias in predator-prey studies, with much greater focus on prey behavior rather than the behavior of predators. As with prey, predators are under evolutionary selection

pressure to forage optimally, although there has been relatively little work studying the foraging behavior of predators searching for (Ioannou et al. 2008), attacking (Cresswell and Quinn 2004), and consuming (Rode et al. 2013) prey that live in groups. In some cases, predators have appeared to have evolved to exploit the grouping and social tendencies of their prey (Rieucau et al. 2015; Rode et al. 2013), even in carnivorous plants (Bauer et al. 2015). The confusion effect and increased conspicuousness of larger groups suggests that predators are under considerable cognitive constraints in predator-prey interactions. The reduced success from the confusion effect should result in a preference for attacking smaller groups (Cresswell and Quinn 2004), but the difficulty in detecting smaller groups constrains the choice of prey available; frequent, but relatively unsuccessful, attacks by predators on larger groups may result in a greater net intake rate compared to maximizing success per attack. Predators may respond to the reduced attack success from confusion and group vigilance effects by spending a greater proportion of their time foraging, so that overall predation rates remain constant. In contrast, they may shift their diet choice to nonsocial prey species that are more profitable once the difficulty in finding and attacking aggregated prey is considered. A full understanding of predator-prey interactions needs a balanced approach where the behavior of predators is also studied, ideally through both theoretical and empirical approaches.

Groups and categories are the elements of social organization in human societies of any size. Whereas the term ‘group’ primarily refers to sets of identifiable individuals, the term ‘category’ primarily refers the mental representation to the building blocks of the social world. Social organization and its mental representation have co-evolved to striking degrees of complexity; yet, simple – even crude – behavioral patterns such as ingroup-favoritism or parochial morality persist.

Humans are social animals, both in their dependency on interaction with individual conspecifics and in their embeddedness in a social structure comprising groups. The nature of these groups varies greatly with ecological, economical, and historical conditions, making it difficult to uncover the essential characteristics of a group-shaped psychology. Studies of the fossil record and surviving hunter-gatherer societies suggest that hominid social life has long been hierarchically organized. Small units, such as temporarily pair-bonded mates and their close kin, are vital for reproduction; bands comprising a few dozen individuals cooperate in hunting, gathering, and shelter-making; communities comprising multiple bands share a language or dialect, and they may intermittently congregate for ritual activities or common defense. This multilevel social organization has evolved during the Pleistocene, and it distinguishes the only surviving human species from the great apes and other social animals (Layton et al. 2012; cf. Darwin 1871).

Evolutionary psychology seeks to understand how and why this prevalent social organization obtained its present form, and inasmuch as the properties of human social organization are functional, what are the adaptive problems they have solved. Moving to the individual human being as the unit of analysis, evolutionary psychology explores elements of cognition, affect, and behavior that can be properly understood only with reference to the evolutionary legacy of past generations.

With regard to the first question, research highlights the co-evolution of neocortical size, mental

capacities, and social organization. Compared with other primates, humans can keep track of a greater number of individual conspecifics, who they are, and, more importantly, how they have acted in the past. Humans can even represent and keep track of those conspecifics who are currently out of sight, often for a long time, and even the deceased. From this knowledge, humans can compute expectations about future behavior and choose between aggression and appeasement, trust and suspicion, pursuit and avoidance. The complexity of these perceptual, memorial, and executive functions is correlated with the size of the neocortex relative to total body size over living species of social animals, and, very probably, over extinct hominid species in evolutionary time (Dunbar 1993). The extraordinary evolution of the human brain is thus intertwined with the complexity of the social organization humans can afford.

A key correlate of advanced psychological functioning is the human capacity to sustain a sophisticated social organization while being able to tolerate very low population density – lower than in any of the great ape species. Bands of hunter-gatherers can roam over large territories, exploiting scarce resources, while occasionally congregating with other bands to affirm shared community identities. Shared language and ritual practice afford community cognition, affect, and behavior. Although some of these shared psychological features reside within the individual and may remain unexpressed (e.g., certain types of affect or elements of the self-concept), many features are expressed in a way that signals shared group identity to others. The evolutionary bedrock of shared identity is genetic relatedness (Dawkins 1976). Social structure is often superimposed on and often correlated with genetic distance, but sometimes it is not. Humans have developed cross-cutting social categories that further complicate social structure. Many hunter-gatherer communities subdivide into clans and totem-defined structures that mimic sympatric bands, by, for instance, imposing taboos on endo- or exogamy, but that are, from the outside observer's perspective, arbitrary (Stanner 1965).

While the hierarchical and multilevel organization of social life is a human universal, its observed forms vary greatly. The flexibility of the social brain and especially the ease with which it creates, changes, and eliminates categories or groupings spawns ever-new structures. The minimum criterion for a social structure to become mentally represented and socially consequential is a signal that communicates inclusion versus exclusion. The totem-based clan is the evolutionary archetype of the influential minimal-group paradigm (MGP) in social psychological research (Tajfel 1970). The MGP mimics social groups or categories that have no basis in genetic relatedness, differential familiarity, or intended future interaction. Research participants are categorized at random, with the only mark of distinction being a quasi-totemic label, such as “The Greens” or “The Blues.” After the typical hour-long experiment, participants are disbanded. In contrast, many arbitrary marks of group belongingness in the wild are irreversible, such as circumcision.

Despite its skeletal and fleeting nature, the MGP produces many of the shifts in cognition, affect, and behavior observed among groups in the field. Most prominent among these phenomena are perceptual contrast and assimilation effects (cognition), ingroup love and positive social identity (affect), and ingroup cooperation versus outgroup competition (behavior). Moving to the second question with the individual as the unit of analysis, we can now consider the three sets of phenomena in turn. Cognitively, the categorization of people into mutually exclusive groups leads to the accentuation of intergroup differences where such differences exist (contrast). If, for example, differences in body height covary with an arbitrary criterion of demarcation, the shorter ones will be collectively viewed as shorter and the taller ones as taller than they would be in the absence of such a criterion. At the same time, individual differences within categories are minimized (assimilation) (Krueger and DiDonato 2008; Tajfel 1969). Affectively, categorization affords identification with those who are like us, even if by label only. In turn, this shared positive affect affords a sense of positive social identity, which extends – usually in mitigated form –

positive self-sentiments to the group (DiDonato et al. 2011) and inversely reflects positive features of the group back to the self (Van Veelen et al. 2016). Behaviorally, categorization affords coordination and cooperation with ingroup members, which, in turn may set the stage for group selection effects over evolutionary time (Wilson 1975).

A minimally sufficient theoretical account to explain the correlated patterns of categorical ingroup perception, ingroup love, and ingroup cooperation (Balliet et al. 2014) assumes that most people possess positive self-images, which they selectively project to ingroups but not to outgroups (Robbins and Krueger 2005). This differential projection results in comparatively positive ingroup perceptions and a comparatively high level of trust in ingroup members (Brewer 2008; Krueger et al. 2012). These models, built on assumptions about learning and inductive reasoning, do not require that people actively compare ingroups and outgroups. Learning about ingroups is sufficient so that competition with and discrimination against out groups can begin as a mere byproduct of parochial learning.

Whereas most social psychological theories assume – and show – that the social or arbitrary introduction of criteria for categorization triggers multifaceted psychological discrimination, some basic distinctions arise from even simpler processes. Human infants are highly sensitive to human and human-like faces. An innate positive response is available, providing a stepping-stone for the building of a mental archive of familiar faces. Infants quickly learn individual identities and thus person-to-person differences. The proximal benefit is that they know from whom to expect love and protection. As a result of this identity learning, infants pick up any variable that is correlated with identity, such as sex and race. Computerized simulations of such learning suggest that it is not necessary to introduce infants to ideas of sex or race; they will induce them from observed patterns of variation (Kramer et al. 2017). The appearance of an individual's face varies somewhat from occasion to occasion, depending on the lighting, the angle of viewing, or the observed person's mood. The learner's challenge is to abstract identity from these

variable observations. However, a person's identity does not cross gender or racial boundaries once it is detected – in most cases. Therefore, sex and race information is implicit in identity information and can be easily extracted. Once the infant (or the algorithm) harvests a categorical distinction from observation, the door is open for accepting other distinctions between social groups and categories, including those provided by social learning.

The title of this essay, “Groups and Categories,” signals the unsettled nature of these concepts in the behavioral sciences. Biologists and social psychologists tend to prefer the concept of group as a general way of referring to any non-random sorting or the lumpiness of social organization. Cognitive scientists, in contrast, tend to prefer the concept of category, as it supports theories of general category learning, which just happen to include social stimuli. On this view, the lumpiness of the mind is prioritized over the lumpiness of the social world. From an evolutionary perspective, the two concepts are too closely intertwined to allow a strictly separable usage. As we have seen, it seems likely that the physical separation into seen and unseen groups coevolved with the ability to represent seen and unseen categories of greater abstraction. At the present time, there is little reason to assume that one concept preceded the other.

Comprehensive historical analysis of how environmental pressures shaped the development of the societies, playing a key role in the supremacy of the Eurasian peoples, aided by weapons, germs, and steel.

Introduction

Guns, Germs, and Steel, written by Jared Diamond, was published in 1997. The book attempts to answer Yali's question, a New Guinean who quizzed him about how Europeans had colonized New Guinea within 200 years and why

they developed so much goods, but they had little goods of their own. By historical explanation, the book intends to understand the interactions among disparate people and how it shaped the modern world through the reverberations of conquest, epidemics, and genocide. The history's broadest pattern question is why did human development proceed at such different rates on different continents.

One of its main ideas is that all great civilizations have had some things in common: advanced technology, large populations, and complex government forms. The arguments are developed in four parts that cover historical examples of how the environment can interfere in a civilization formation and interaction, how and why they evolved from hunter-gatherer to food-producer societies, how the food production has fostered a complexification of societies, and finally how these elements made possible the domination of the Eurasian peoples over the others.

Environmental Pressure on Very First Civilizations

The author investigates, in a Darwinian perspective, the influence of environmental pressures on the formation of human societies, from *protohumans* to the last 13,000 years of history. In analyzing the societies' diversity on the Polynesian, Diamond provides clues to understanding the plural formation of the civilizations. The author investigates the main factors that contributed to further technological, economical and social development of some societies, especially the world supremacy of the Eurasian people in terms of wealth and power. The climate and geography conditions of the very first civilizations were very similar. These aspects shaped the way to acquire resources for survival. Understanding the development of technologies is determinant to discern the capacity of some people to dominate others. Even there were people in similar environmental conditions, the rise of practices like food production by agriculture instead of hunt-gather lifestyle allowed the development of societies and their technologies.

Food production spreads at different rates on different continents. Middle East and Chinese peoples were the first farmers; they started to control nature interrupting the environmental cycle to produce wheat and barley and rice, respectively. New Guinea type of food, taro roots, has a difficult process to grow and has some disadvantages: it is necessary to plant taro roots one by one; it can't be stored because it rots quickly and it is low in protein. Besides, the hunt-gather lifestyle wasn't economic and took a lot of effort and poor results. In most places where farming emerged, a relatively large advanced civilization followed.

Another element of the societies' development was the animal domestication. This package was mutual beneficial for humans, animals, and plants. When human started to control their moving, feeding, and breeding, it was possible, without hunting, to have meat supply, milk, muscle power to the plows, and leather. Thus, exceeding food production could feed the animals, which would aid in the production of more food because of their strength and also the ability of their excrement to fertilize the soil. The best animals to domesticate were those plant-eating and sociable mammals, as ox, horses, pigs, sheep, and goats, native from the Middle East. The only domesticated mammal in New Guinea was the pig, which can't produce milk, leather, or muscle force for plows.

Diamond assumes that it is the shape of the continents, their crops, and their animals that allowed some cultures to flourish while others were left behind. Also the type of farming was most important than only farming, because most productive and nutritious crops allowed most productive farmers. The people in New Guinea didn't advance technologically; they spent too much time and energy feeding themselves.

From Germs to Guns and Steel

Therefore, two main arguments for the development of societies are presented: (1) surplus of food production allowed the social division of work and the raising of class specialized in other activities and (2) human contact with animals allowed

interactions with germs, which caused several diseases, an important element to understand colonization processes. The crops, the animals, and the increasing food production started to feed new social groups: the artists, the inventors, and the soldiers. Thus, years of agriculture development allowed to evolve the writing, the new technologies, and a central government and religion. The writing emerged independently at the Fertile Crescent, Central America, and China, where there was plenty of food and cultural interactions. This knowledge facilitated communication, dissemination of information, and other technologies, placing literate civilizations ahead of others. Technology is developed through two processes: creation and diffusion. Creation is more difficult because it involves high cost and requires more time. Diffusion, in turn, primarily requires a contact between peoples for the exchange of knowledge. In addition, technology is an autocatalytic process, that is, the more it develops, the greater its advancement potential. In this way, technological development, as well the political complexification, depends on the contact between independent civilizations and higher food production. Food production is related to technology, as larger population increases the exchange of knowledge and the chances for geniuses.

In turn, germs as well evolved with writing, guns and political organization as a modern agent of conquest. Europeans and Central America Indians had a developed civilization, with central government, writing, and food production; however, genocide was not caused only by guns and steel but predominantly by the diseases brought by European. The dominance of European societies occurred mainly because they had the writing, complex government, technology (as guns and steel), and germs. Diamond's arguments highlight that the differences between the civilizations do not derive from the biological capacities of the peoples who formed them but were primarily determined by the environment. For example, Yali's people did not produce metal or steel tools and did not use writing, and their social structure wasn't complex. Besides, their land, geography, and plant and animal species did not allow a development of a complex society. Similar patterns were found in

other civilizations. They were limited by environment dispositions, such as low diversity of food sources and fragmented or isolated lands, precluding the populational growth and the social development. Furthermore, the low cultural exchange with other people and isolation hindered the high technological development.

Conclusion

The civilization collisions created reverberations that have still not died down after many centuries and that remain continuing in some of the world's most troubled areas today. There are four main types of differences to understand the development of civilizations: first, continental differences in the plant and animal available species; second and third, the rates of diffusion and migration among and between the continent, which allowed the knowledge of new technologies and the political and linguistic progress toward its unification; and fourth, continental differences in total area or population size, because they mean potential inventors, competing societies, and innovation. In short, the book indicates that some environments provide better starting materials and favorable conditions for utilizing inventions than do others. The culture and the individual, although they are important elements in history, are scarcely relevant for the purposes of the book, because it would be difficult to interpret history's broadest pattern in terms of a few individuals. *Guns, Germs, and Steel* is ultimately a comprehensive history analysis. Its subject matter is not just of academic interest but also of overwhelming practical and political importance.

The human gut microbiome is a community of roughly 40 trillion bacteria, fungi, archaea, and protozoa which reside within the human gastrointestinal tract. Variations in gut microbiome composition have been implicated in a variety of psychological, physiological, and behavioral traits.

Introduction

A variety of environments, including many human organs, contain within them communities of microorganisms, including bacteria, fungi, archaea, protozoa and viruses. This community is collectively referred to as the microbiome or microbiota. Traditionally, the term microbiota was used to refer to the community of organisms, and microbiome to refer to the collective genomes of organisms within those communities. While the term microbiome can still refer to a set of collective genetic material, these two terms are also now used synonymously to refer to the community of organisms within a given environment (Ursell et al. 2012). The human gastrointestinal tract contains roughly 40 trillion microorganisms which collectively form the

gut microbiome (Sender et al. 2016). Of these organisms, bacterial species are the best understood, of which there are approximately 1000 species, belonging to 4 dominant bacterial phyla: *Firmicutes*, *Bacteroidetes*, *Actinobacteria*, and *Proteobacteria* (Guarner and Malagelada 2003).

Human gut microbiomes are established at birth, when an infant is seeded with microbes from the mother's vaginal canal, skin, and feces. Infants born via caesarean section present with different compositions of gut microbes, which resemble microbes found on their mother's skin, compared to those born vaginally whose gut microbiomes more closely resemble the mother's vaginal canal (Dominguez-Bello et al. 2010). These caesarean-associated early gut microbiomes have been implicated in the risk of later diseases such as celiac disease, type 2 diabetes, and asthma (Mueller et al. 2015). The gut microbiome is further colonized during breastfeeding and continues to change throughout development in response to the environment. By 3 years of age, the infant gut microbiome is structurally similar to those found in adults (Palmer et al. 2007).

There is a lot of individual variation in gut microbiome composition, though those differences remain relatively stable over one's lifespan (Costello et al. 2009). However, this stability can be altered by diet, disease, and the use of medications like antibiotics (Becattini et al. 2016; Power et al. 2014; Turnbaugh et al. 2009).

Microbiome diversity is understood using metagenomics, which uses bioinformatic techniques to identify multiple species from environmental samples of large amounts of DNA. In 2012, a reference database for the human gut microbiome was completed, as part of the first phase of the Human Microbiome Project (Human Microbiome Project Consortium 2012).

Symbiosis and Evolution

Gut microbes exist in a symbiotic relationship to their human hosts. Many are thought to be commensal, imparting no direct harm or benefit to their human host. Other relationships are mutualistic. For example, some gut

microorganisms help to metabolize compounds so that human hosts can access otherwise inaccessible nutrients. Others digest carbohydrates, ferment dietary fiber, and synthesize vitamins, fulfilling important digestive roles (Turnbaugh et al. 2007; Liang et al. 2018). Parasitic relationships also exist where microorganisms in the gut harm their human hosts, causing disease and, in extreme cases, death.

Mutualistic relationships suggest a persisting evolutionary history between microbiomes and their hosts, as each relies upon one another for vital functions, and thus are thought to have coevolved. This type of coevolution is sometimes understood as a holobiont – an entity which includes both the host (macroorganism) and its symbiotically related microorganisms (microbiomes). A related concept is the hologenome – which in this case is the complex of genomes of microbiomes and their hosts (Rosenberg 2013).

There is emerging evidence that gut microorganisms can influence human behavior. This has led some researchers to consider whether the evolution of some human behaviors can be explained in light of the benefits to their associated microorganisms (Turnbaugh et al. 2007). For example, Alcock et al. (2014) have theorized that food cravings and eating behaviors with negative human health impacts have originated as a mechanism by which some microbes acquire nutrients and defeat competitor microbes in the gut, in order to maintain their own existence.

Human Physiological and Disease Associations

Differences in the composition of the gut microbiome have been implicated for various human diseases. Microbiomes associated with disease states are termed “dysbiotic” and often display reduced diversity, along with under- and overrepresentations of certain bacterial phyla. Inflammatory bowel disease, which includes Crohn’s disease and ulcerative colitis, has been associated with decreased overall microbial

diversity, as well as compositional differences when compared to healthy individuals. It is thought that these diseases develop from an interaction of gut microbes with the mucosal immune system (Kostic et al. 2014).

Asthma and many allergies are also associated with compositional differences in the gut microbiome. Mechanisms of gut microbiome alteration in these cases may be due to diet or because of lack of early life infections which alter the T-cell response in immune system (the hygiene hypothesis) (Shen and Wong 2016).

The gut microbiome has also been implicated in cancer, with both *Bacteroidetes* and *Clostridium* associated with increased tumor growth rate and fewer tumors observed in germ-free (thus microbiome free) rats and mice. Specific bacteria, such as *Helicobacter pylori* (associated with gastric ulcers), are thought to contribute to cancer with epithelial injury and inflammation. Other kinds of bacteria are thought to prevent tumor formation, such as *Bifidobacteria* and *Lactobacillus* (Schwabe and Jobin 2013).

Individuals with a higher relative abundance of *Firmicutes* rather than *Bacteroidetes* are more likely to be overweight, and humans who have lost weight through dieting reduced their increased abundance of *Firmicutes* (Ley et al. 2006). However, it is not known in this instance whether microbiome composition is a cause of obesity or obesity is a cause of microbiome composition. In order to investigate this further, experimental manipulations in animal models have extensively addressed the obesity question (discussed below).

Human Behavioral Associations

Interestingly, the human gut microbiome has also been implicated in many behaviors and mental capacities. The proposed mechanism of influence is the gut-brain axis, which encompasses a bidirectional pathway between the central nervous system and the digestive system. This axis includes the vagus nerve, hormone secretions, inflammatory molecules, and signalling molecules (Carabotti et al. 2015).

The gut microbiome is thought to influence mood via its effects on serotonin and tryptophan – hormones which regulate stress responses and influence cognition. There is some evidence that people with depression have altered microbial compositions in their gut, though no differences in species richness have been observed (Dash et al. 2015). There is also some evidence that probiotic usage can decrease the likelihood of depressive and anxiety-related symptoms in humans (Foster and Neufeld 2013).

A large number of children with autism also present with gastrointestinal problems, and an increase in the relative abundance of *Clostridium* has been observed in autistic children. However, interventions on the microbiome via diet and probiotic use have so far proved unsuccessful for the treatment of children with autism (Chen et al. 2013).

A major issue with associative studies is identifying the causal structure of each association. Microbiomes may be causing human differences in behavior, psychology, and disease, or it may be that human behaviors and human diseases causally impact upon microbiomes. It is also possible that a third factor is a common cause of both microbiome compositional differences and the trait of interest. For instance, autistic children are often picky eaters, and so differences in diet may account for differences in microbiome composition. Relatedly, obese individuals often have markedly different diets and lifestyles compared to nonobese individuals.

For this reason, researchers have used animal models in an attempt to uncover the causal processes underlying gut microbiome associations. Animal models provide the advantage in that microbiomes may be manipulated and other confounding variables minimized.

Evidence for Behavioral Influences in Animal Models

Animal models, particularly using rodents, have been used to make inferences about the causal role of human gut microbiota. Germ-free (GF) mice are most often used, which have been birthed

surgically and raised in sterile environments, meaning that they have no gut (or other) microbiomes. GF mice are then artificially colonized by the microbiome of interest. Fecal matter (representing the donor gut microbiome) is transplanted surgically into the host GF mouse via gavage in a process termed fecal microbiota transplant (FMT). The fecal transplant is sourced either from another mouse with a particular phenotype of interest (mouse-mouse FMT) or from a stool provided by a human donor with a phenotype of interest (human-mouse FMT). Transfer of phenotype from both donor mice and humans has been demonstrated most compellingly for obesity. Recipient mice which receive FMTs from obese mice, or from obese humans, become obese themselves, suggesting strongly that the gut microbiome is a causal factor in the development of obesity (Turnbaugh et al. 2009).

The success of transfer of phenotype studies for obesity has spurred experimental research investigating other microbiome associated traits in humans – including human psychological attributes. These include developmental disorders, such as autism, and mood disorders like anxiety and depression. To date, there has only been one successful transfer of behavioral phenotype study using human donor FMTs. FMTs from depressed humans into antibiotic-depleted rats induced depression and anxiety-like behavior (Kelly et al. 2016). Mouse-mouse FMTs have also been shown to decrease anxiety-like behaviors (Bercik et al. 2011). Other evidence for the microbiomes influence on behavior comes from indirect interventions on the gut microbiome. Autism-like behaviors were observed in mice which had in utero disruption, altering the microbial composition of their guts (De Theije et al. 2014). Probiotic administration has been shown to decrease anxiety and the severity of stress response in mice, thought to act indirectly via changes in microbiome composition (Sudo et al. 2004; Diaz Heijtz et al. 2011).

One problem with the animal model approach is that complex psychological traits are measured using behavioral proxies in mice and rats. For instance, tests of depression are made using the forced-swim test, where animals are placed into a

water-filled cylinder and their attempts at escape are timed. Individuals who stop swimming or “give up” after a shorter period of time are deemed depressed, compared to those which continue to try and escape for longer. Anxiety tests include recording the amount of time an animal likes to spend in an exposed environment (prominent examples are the light-dark box test and the elevated plus maze). The least amount of time spent in a very light or exposed environment, the more anxious the animal is thought to be. Autistic-like mice are characterized by reduced socialization, increased anxiety, fewer vocalization, and obsessive behaviors like grooming and marble burying. Given these limitations, some (Hooks et al. 2019, Lynch et al. 2019) have questioned some of the scientific conclusions made about microbiome causality, suggesting that claims about the influence of the human gut microbiome on behavior have been overblown or at the least are premature.

Concluding Remarks

The human gut microbiome is the most well-studied and complex microbial community on the human body. Without these microbes, humans would be unable to perform many vital metabolic functions, and so many microbes persist with their human hosts in a mutualistic symbiotic relationship. Differences in the relative abundance of microbes, or microbiome composition, along with increases or decreases in overall diversity, are implicated in a number of health in disease states, such as inflammatory bowel disease, cancer, obesity, allergies, asthma, autism, and mental health. The gut microbiome is thought to influence human behavior via the gut-brain axis, and some human behaviors are hypothesized to be due to the evolutionary interests of gut microbes.

Associative evidence for physiology and behavior are potentially confounded, and so manipulative experiments colonizing germ-free rodents with microbes provide the majority of evidence for microbiome causality. These experiments have successfully demonstrated manipulations on the microbiome resulting in disease states, obesity, anxiety, depression, and

autism-like behaviors. However, critics of these studies point out that murine behavioral analogues are not sufficient to demonstrate the causal role of microbiomes in human health, disease, and behaviors.

Definition

The changing of a habitat for a given species, whether voluntarily or involuntarily.

Introduction

Much of the way we are shaped by evolution is indicative of the kind of environment we had to survive in. Early records show that we, as humans, had to survive at one point in trees as we often see modern primates do. Many primates today are confined to forests, whereby they have developed

mechanisms physiologically to be able to climb high distances, especially given the usage of their opposable thumbs. In addition, the diet that keeps them nourished is very indicative of living in trees, such as having to seek out fruits like bananas that may grow at a higher altitude. Therefore, a major question for someone who does not understand the concept of evolution is how we are living as *Homo sapiens* today despite there still being monkeys in the wild. Many people choose to understand evolution as a “progression toward perfection.” This is a common misconception – evolution is not a progression toward perfection. In fact, the idea of “perfection” is highly debatable – what exactly constitutes a “perfect” organism? Evolution is simply biological and psychological changes in an organism that are best suited and adapted for survival in their respective environment. A classic example is Darwin’s discovery of finches on the Galapagos islands. Their beaks are by no means perfect, but their beaks were also well-suited to be able to eat the kinds of foods that were best suited for that respective bird’s diet. A similar concept is true between chimps and humans – the reason chimps continue to look the way they do is due to the environment that they are in. They are in an environment whereby getting to high elevations is essential to not only find food sources but to also have a better visual scope of the environment around them and avoid predators. Humans, on the other hand, do not have the mobility and grip strength that is evident in primates, as we have a much harder time

climbing than do many modern monkeys. We also stand in an upright posture with our spines straight, and walk with what is called *bipedal locomotion*, or the ability to walk on two legs. Monkeys often depend on their arms as a means of locomotion, as is evident in the way many primates walk, such as gorillas. This difference, however, is by no means a coincidence, nor did we evolve such a difference because of “perfection.” The difference lies within specifically habitat change. Given that we have so much in common genetically with modern primates, there had to have been some kind of change or a point at which a divide was necessary and occurred to have so much genetic similarity but such a monstrous difference in behavior and physicality. The bigger question that evolutionary scientists are still trying to figure out to this day is precisely, “Why and how did this change occur?”

Our Original Habitat

Oddly enough, one of the key components that demonstrates how our early ancestors may have lived in trees is exhibited by our shoulder development. Genetically, we are most similar to chimpanzees and also share their shoulder structure most similarly. Despite us sharing most of our genetic similarity with apes, it seems as though our shoulder development is actually more similar to orangutans than other apes, suggesting that at some point we had a mechanism by which we had to swing between trees in the way orangutans do. Through studying evolution, we must operate under the assumption that no physiological change is the result of a mere coincidence, rather, there must be some adaptive purpose to have developed the kind of structure the organism did. In this case, there must be some reason why we share so much genetic similarity with other apes, but our shoulders specifically seem to model orangutans that swing between trees as compared to heavier apes (Young et al. 2015).

If we did indeed live among the trees, then an obvious question of course would be why we ever had a reason to move out if our bodies were already accommodated to living in those conditions for

survival. The answer is not fully understood, although there are an abundance of theories that attempt to explain why through various means of measurement. As will be discussed in later chapters, there are numerous popular theories such as climate change or simply being pushed out by other animals that could explain why we eventually moved out of the trees after successfully living in them for such a long period of time. (Potts 1998)

The climate theory, in short, essentially states that there are constant fluctuations in our climate that can have profound effects on our environment. The theory also states that the fluctuations in climate are more dramatic than ever, especially with the advancement of the industrial revolution and the ever-increasing population, having a more profound effect on the environment than ever. However, we also see climate change far before human civilization, whether due to catastrophes such as volcanic eruptions, the supposed meteor that wiped out the dinosaurs, or even the last ice age that wiped out vegetation and livestock across many continents. Therefore, it is suggested that perhaps some kind of major catastrophe happened at the time that would result in a change in the local environment. Thus, a lack of vegetation or even deforestation resulting in a lack of trees would have made survival infinitely harder for primates and early hominids, and thus they likely decided to migrate further down to look for resources that would be scarce at higher elevations (Demenocal 2004). This also likely resulted in a *population bottleneck* or an event that significantly decreases the population of a given organism. These changes likely resulted in the vast majority of our species dying from either being unable to survive in the trees due to lack of resources or moving onto the forest floor and being unable to survive due to new predators and an unfamiliar environment (Potts 1996). Those that did survive, however, likely were eventually able to migrate out onto the African grasslands, where they then started experiencing evolutionary change over the course of millions of years to adapt to their new environment.

Another such theory is that we simply got “bullied out” by our ancestors which would

eventually become modern day primates. It is possible that they gained some kind of evolutionary advantage that allowed them to get resources faster than early hominids could, giving them no choice but to move to another location to ensure survival. Again, those that could survive did, but it likely resulted in a massive decrease of the population whereby migrating to a new environment and reproducing with viable mates was the only way that the species could survive. As a result, the species slowly but surely had to make adjustments neurologically and physiologically to accommodate for an environment that they were not evolutionarily suited for, similar to the *evolutionary mismatch* effect. (Foley 1994)

Given that grasslands were often much higher in visibility due to the lack of obstruction from trees and a wider horizon, it became pivotal that our vision and hunting skills change. Hence, we developed bipedal locomotion as a more efficient means of traversing the grasslands and being able to hunt our prey. We adapted from having short bursts of speed and having the strength to be able to climb trees and instead endure long distance running to tire out our prey, as well as our shoulders changing to be able to accommodate for weapon making and throwing. It was precisely this change that paved the way for eventual *Homo sapiens*, given that with the ability to make weapons, we evolved from a creature that was confined to trees and using our body as our means of hunting prey and instead creating objects that we can attack prey with from a distance – maximizing resources and food and minimizing risk. With this cycle came a population resurgence and therefore eventually the entire hominid species moving out into the African savannah.

The African Savannah

The savannah represented a radical departure from the forest that we had previously lived in, and therefore the reason we see ourselves as so different from chimps is because of that divide

that occurred to keep them in trees and us on the grasslands. The chimps had no reason to have to change given that whatever the reason may be (climate change, being pushed out by predators or our ancestors, or another reason we have not been able to deduce), they were able to survive in the trees whereas early hominids could not. While the hominids' new environment requires new means of adaptation to be able to hunt different kind of prey on a different terrain, the primates kept doing what they had been doing all along. This, in essence, is the answer to why we have evolved into *Homo sapiens*, but monkeys still exist – they simply had no reason to change given that they continued to live in the environment that their bodies were always suited to, as they continue to do today. Hominids were forced out, and therefore the evolutionary changes we see in ourselves today that differentiate us from primates are remnants of how we would survive on the savannah (Reed 1997).

Savannahs typically have a wider horizon, and therefore our vision became essential to not only avoid being killed by predators but to more easily seek out prey that represented food and a means to survive as a group. As such, our spines began to straighten out rather than have curvature and we developed *bipedal locomotion*. Not only did this allow us to traverse long distances, but it made a huge difference in terms of our vision and even our communication. Instead of lifting our heads to look at what was in front of us, we now could look at our surroundings with ease and could turn our heads horizontally in a manner that was not possible before. This was no coincidence, of course, as the savannah is often called “flatlands” for their constant altitude and lack of elevation – generally, it was important to be able to have a wide scope of view of the entire landscape and to see as far as the horizon to be able to hunt for prey. Not only did this structural change help our vision, but it also helped us communicate with other hominids. By being able to look directly at their face, face-to-face communication became much easier, by being able to read emotions and eventually develop language and dialects that allowed for

more coordinated execution of group activities. As a result, enhanced communication came which would eventually lead the way to more advanced concepts such as music, stories, and much of the art world we see today in the form of human creativity.

Conclusion

Our habitat change was essential to the way that we have developed physiologically as *Homo sapiens*. We now stand in an upright position because of *bipedal locomotion*, which gave us an enhanced and extended scope of vision, as well as enhanced communication which led to the development of speech and language. Getting out of the trees also allowed for free use of our upper body that was previously essential to be able to walk as well as swing from tree to tree. Our shoulder muscles then evolved to be able to do things such as create weapons and more importantly throw them, maximizing our potential as predators in the environment to hunt prey. The ability to throw objects was essential to survival especially on the African savannah, not only given the newfound predators and the lack of obstruction from trees, but also simply to maximize reward by attacking animals from a distance, but also minimize risk by avoiding getting close to potentially dangerous animals. In short, many people fail to understand the concept of evolution by not comprehending why chimps are still in the wild today, but humans exist alongside them. This difference is explainable by our division from chimps for a number of possible reasons, such as climate change or being pushed out by other predators or ancestors. Ultimately, habitat change was paved the way for us to evolve into the *Homo sapiens* we see ourselves as today, physiologically and with our remarkable ability at communication and cooperation.

Definition

Habituation is a process of diminishing responsiveness due to the presentation of a repeated stimulus.

Introduction

Habituation constitutes an essential process of behavioral adaptation, as it assists in filtering out the large amounts of information received from the surrounding environment that are likely irrelevant or less important, thus shifting attention to more important to survival or urgent information. The latter gives an evolutionary advantage as a result.

Theoretical Background

Several influential nonassociative theories have historically been proposed Thompson (2009). These theories constitute the early work of Sokolov (1960) and Wagner's (1979) revision of Konorski's Gnostic Hypothesis, and Groves and Thompson's (1970) dual process theory.

Sokolov (1960) was the first to propose a comprehensive theory of habituation ("*Stimulus-Model Comparator Theory*"). In short, Sokolov's theory stated that when a stimulus appears repetitively, the brain cortex forms a model (or a memory) of the stimulus. Each incoming stimuli were compared to the model and if the incoming stimulus matched the model, responding was inhibited; otherwise, an orienting response was evoked. The exertion of inhibition was thought to yield habituation; thus, habituation was perceived as purely inhibitory. Even though Sokolov's work intrigued a great bulk of follow-up investigations in habituation in the human kind, the theory was not applicable to animals who do not possess a cortex, contrary to the dual process theory.

Another comparator theory constitutes the work of Konorski's on habituation which shared many similarities with Sokolov's theory. Wagner (1979) revisited Konorski's ideas but he concentrated on the roles of short-term memory and

associative mechanisms. A stimulus is carried by afferent/sensory neurons toward a memory system, the Gnostic assembly, and to the arousal system. With repeated stimulation, a gnostic unit is formed, that is a near accurate neuronal model or memory of the stimulus. As this model develops, it increasingly activates an inhibitory system that inhibits the arousal system, consequently causing habituation. Wagner added a process mediator, an associative network where contextual cues have to pass through in order to excite stimulus models in memory and a process of transient memory (short-term memory). In short, what these scientists advocated is that long-term habituation requires the storage of a stimulus in long-term memory and that it is associated with external cues for retrieval from long-term memory.

Finally, the most prominent nonassociative learning theory was proposed by Groves and Thompson (1970). Neurophysiological concepts were combined with concerns of human ethology and evolution to create the *dual process* theory. This theory advocated that repeated stimulation would produce two independent processes that could both be active at the same time; decreased responsiveness (habituation) or increased responsiveness (sensitization). The authors believed that the two processes take place in different parts of the nervous system. Scientists believed that habituation took place in the so-called S-R system (reflex arc) that controls reflexes whereas sensitization occurred in the "state system" which is responsible for the level of readiness to respond. The state system requires arousal to become activated while the S-R system is activated with the presentation of an eliciting stimulus. Further, habituation is thought to be stimulus specific and involves learning, in contrast to sensitization which is not highly specific and does not require learning. However, both are of relative permanence; they are expected to decay at the absence of stimulation. Contrary to Sokolov's model, the *dual process* theory does not propose an inhibitory system.

Nevertheless, all these studies of cellular processes which facilitate learning and memory, which were mostly held in invertebrates, most

certainly add to the understanding of the underlying physiological processes of learning in the majority of living animal organisms, but mechanisms such as habituation and sensitization are far more complex and necessitate further exploration.

The Nature of Habituation

Habituation constitutes an essential process of behavioral adaptation, as it assists in filtering out the large amounts of information received from the surrounding environment that are likely irrelevant or less important, thus shifting attention to more important to survival or urgent information. The latter gives an *evolutionary* advantage as a result. Habituation is the simplest form of non-associative learning and it can be defined as a decline in behavioral responsiveness to the continual presentation of a stimulus. While there is a strong response initially, the strength of the response reduces and eventually disappears with repeated stimulation. The reduction in responsiveness is neither the result of motor (muscle) fatigue nor sensory adaptation; however, it is likely to be disrupted when another strong stimulus appears (dishabituation). Other factors influencing habituation include stimulus repetition, interstimulus interval, and stimulus intensity. These factors are determinant of whether short- or long-term habituation will occur. Short-term habituation is characterized by rapid stimulations with short intervals in between, habituation is observed early; however, it is short-lived as soon as stimulation ceases. On the other hand, long-term habituation is characterized by fewer stimulations over longer periods; habituation is slower but its effects are long-lived as recovery is delayed.

In addition, in earlier writings, habituation was thought to only have short-term effects (Hinde 1970); however, existing literature has demonstrated that its effects can last long. Apart from its simplicity, habituation is thought to be ubiquitous; it is both a highly automated yet learned phenomenon occurring in the central nervous system (CNS) of all animal species, ranging from single-celled protozoans to humans Thompson (2009), with studies demonstrating its occurrence

in plants as well Gagliano, Renton, Depczynski, Mancuso (2014). Thompson and Spencer (1966) presented a list of nine parameters of habituation, shared by all species. A tenth parameter was added to the list of behavioral characteristics of habituation by Rankin et al. (2009) and are all presented as follows:

1. Given that a particular stimulus produces a response, repetitive applications of that stimulus will result in a reduced response (habituation). Most of the times, the decrease is a negative exponential function of the number of stimulus presentations.
2. If the stimulus is withheld, the response tends to recover over time ("spontaneous recovery").
3. After a multiple series of stimulus repetitions and spontaneous recoveries, habituation becomes more rapid ("potentiation of habituation").
4. The more rapid the frequency of stimulation, the more rapid and/or more pronounced is habituation.
5. The weaker the stimulus, the more rapid and/or more pronounced is habituation. Stronger stimulation might yield no significant habituation.
6. The effects of habituation training may proceed beyond the zero or asymptotic (minimum level of response) response level.
7. Habituation of response to a stimulus displays stimulus generalization to other stimuli.
8. Presentation of another strong stimulus results in disruption or recovery of the habituated response ("dishabituation").
9. After repeated application of the dishabitatory stimulus, the amount of dishabituation produced habituates ("habituation of dishabituation").
10. Some stimulus repetition protocols may result in properties of the response decrement that last hours, days, or weeks. This persistence of aspects of habituation is termed long-term habituation.

Importantly, the aforementioned characteristics of habituation were observed and collected

through numerous studies on a variety of species; therefore, they do not imply particular theories or inferences. They could be considered, however, as a detailed definition of habituation.

Several scientists who have studied the process of habituation provide valuable information regarding the underlying mechanisms of habituation and associated processes, demonstrating at the same time its complexity Thompson (2009). It has been noted that the occurrence of habituation is determined and/or influenced by variations in interstimulus interval and by the organisms' ability to generalize and discriminate between the presented stimuli. Additionally, spontaneous recovery is another process thought to influence habituation's maintenance. All these concepts are further analyzed in the section ► [“Interstimulus Interval”](#) that follows.

Interstimulus Interval

The concept of interstimulus interval is frequently encountered within processes of nonassociative learning, specifically habituation and sensitization Petrinovich (1984). Interstimulus interval can be defined as the time interval between the end of one stimulus presentation and the onset of another stimulus presentation. Interstimulus interval experiments were extensive under the work of Davis (1970) on habituation of the acoustic-startle response in the rat. Generally, through Davis's series of experimental studies, it was demonstrated that the length of interstimulus interval, as well as variability (regularity), determines habituation in animals. The author compared the responsiveness of two groups of rats to a 50-ms, 120-db tone of 4000 Hz during pretest, training, and posttest periods. During both the pretest and the posttest periods, both groups of subjects received 300 tone exposures at intervals of 2, 4, 8, and 16 s, the intervals being scheduled in an irregular order. During the training period, both groups received 1000 tone exposures; however, the interval between stimuli was 16 s in one group and 2 s in the other group. Among other findings, greater reduction in responsiveness was

observed in the group who received stimulation every 2 s.

In the second experiment, startle responsiveness was lower following training with regular as opposed to variable interstimulus intervals. Simply put when interstimulus interval is longer and constant, habituation is greater. Also Davis (1970) reported a quite an interesting finding; when rats were tested at 1 min or 24 h later with a variety of interstimulus intervals, habituation was greater for the group that was trained on the 16 s interstimulus interval schedule suggesting, thus, that short- and long-term habituation processes may be distinguishable on the basis of the presentation and the intervals between stimuli. Specifically, it was demonstrated that short interstimulus intervals were involved in the progression of short-term habituation, while long interstimulus intervals were involved in the promotion of long-term habituation. Also, apart from the fact that high-frequency stimulation leads to more rapid response decrement, it results in faster spontaneous recovery as well Leaton (1976).

Similarly, Groves and Thompson (1970) noted that increased frequency should lead to increased habituation in the “S-R” pathway, but in the “state” pathway, it would lead to increased sensitization. All the aforementioned experiments considered together are indicative of the importance of interstimulus interval making it obvious that it can have a major effect on learning; it may delay or improve learning. Lastly, the organism's ability to determine the interval and duration of sensory stimulation is central to sensory processing; therefore, impairments in that domain are likely to interfere with the process of learning.

Variations in the time between the presentations of one stimulus to the next have a determinant effect on the forms of nonassociative learning; habituation and sensitization and the occurrence of long- and short-term habituation are dependent upon the length of interstimulus intervals Leaton (1976). Further manipulation of interstimulus intervals will provide valuable information regarding disruptions in learning processes or even suggestions as to how to enhance learning.

Stimulus Generalization and Discrimination

The concepts of stimulus generalization and stimulus discrimination are encountered within the context of associative and nonassociative learning. *Stimulus generalization* refers to a set of stimuli sharing similar properties with the original stimulus that provoked a response. *Stimulus discrimination* is the ability of an organism to respond only to the original stimulus and not to other similar stimuli.

Both concepts are inherent mechanisms in the processes of associative and nonassociative learning, and for both processes to take place, it is essential that a stimulus model should be stored in memory in order for comparisons with new stimuli to take place.

To begin with, generalization occurs when an organism *produces the same response to different stimuli*. Stimuli who exhibit analogous properties to the stimulus that was originally presented and provoked habituation, are more likely to provoke a similar response, that is habituation. There could be variations in terms of the level of pitch, brightness, loudness, and so on; however, if these variations deviate significantly from the properties of the original stimulus, generalization will not occur; hence, it is more likely that habituation will not occur either Teyler, Chiaia, DiScenna, Roemer (1984). Stimulus generalization of habituation can only be determined when a second habituation series is done with the use of a novel stimulus. With a comparison of the rates of habituation between the original and the novel stimulus, the amount of generalization will be demonstrated. More rapid habituation in the second series would be indicative of generalization, whereas similar rates between the two series would be indicative of a lack of generalization Petrinovich and Widaman (1984).

On the other hand, if stimuli are rather dissimilar than similar, the opposite process of stimulus generalization, the so-called *stimulus discrimination*, will be activated. In *stimulus discrimination*, the organism shows the ability to differentiate between similar stimuli and only to respond to a specific stimulus; hence, the

organism responds *differently* to the two stimuli. *Stimulus discrimination* is particularly important in the process of habituation, as it can be used to dismiss sensory adaptation and fatigue as an alternative explanation of the occurrence of habituation. Further, *dishabituation* is indicative of the ability to discriminate, therefore ending habituation Thompson & Spencer (1966). It is important to clarify, however, that dishabituation occurs due to repetitive stimulation of a completely irrelevant stimulus and should not be thought of as the same as stimulus discrimination. Finally, stimulus generalization is useful because it allows for learning to take place quickly in new situations that share similarities with past experiences and promotes the transfer of skills into similar situations thus saving time and effort. Stimulus discrimination offers assistance in a practical level as well.

Stimulus generalization and discrimination are crucial processes in learning and both are of paramount importance to adaptation. Clearly any organism that lacks such abilities would have minimal chances of survival. There are well-known experiments undergone within the concept of conditioning (Pavlov's and Watson's experiments) that illustrate the stimulus generalization and the stimulus discrimination concepts more elaborately.

Spontaneous Recovery

Spontaneous recovery refers to the recovery of a habituated response. When a sequence of stimulus presentations is interrupted, the object at hand will return to its earlier stage, the behavior will recover over time. In a series of experiments undergone by Rankin and Broster (1992) on the nematode *Caenorhabditis elegans*, mechanical stimuli were delivered at four interstimulus intervals (2, 10, 30, and 60 s) in order to investigate the effect of interstimulus intervals in the development and maintenance of habituation. Results indicated that recovery from habituation was dependent on some factors. One of these factors is the length of interstimulus intervals; it was observed that recovery from habituation was faster when short interstimulus intervals were applied rather than longer interstimulus intervals.

That is, long-term habituation prevents recovery. Also, the rate of recovery varied according to which response level each subject exhibited on the habituation curve. The recovery of animals on the lowest response level appeared to be determined by interstimulus interval and not by the further addition of stimuli. Interstimulus interval recovery rates did not differ even though the number of stimuli the worms received was significantly bigger (60 vs. 10) in the second group. In short what was evident is that the frequency of stimulation during habituation training was the one to determine the rate of spontaneous recovery.

Moreover, Rankin et al. (2009) upon revisiting the characteristics of habituation, originally described by Thompson and Spencer (1966), revised a point concerning spontaneous recovery. It is described in the characteristics that when a sequence of stimulus presentations is interrupted, the object at hand will return to its earlier stage, the behavior will recover over time. Rankin et al. (2009) revised this characteristic by adding that sometimes the response recovers completely, but sometimes it recovers only partially depending on the time frame that recovery was examined.

Further, when stimulus presentations and spontaneous recoveries are given repeatedly, the phenomenon of *potentiation of habituation* is observed. Here, the decrement in response that follows spontaneous recovery (i.e., habituation) becomes gradually more rapid with each application of spontaneous recovery. Moreover, the process of spontaneous recovery can be disrupted with the presentation of a new, strong stimulus, i.e., sensitization.

Lastly, it is crucial to note the importance of spontaneous recovery; it is the second way, with stimulus discrimination being the first way, to distinguish sensory adaptation and fatigue from habituation. With regards to learning, this process demonstrates that even though a response might disappear, it does not necessarily mean that it has been withdrawn from memory and that it will never reoccur.

Experiments on the lowest living forms illustrate the phenomenon of spontaneous recovery and those indicate that spontaneous recovery is highly determined by the frequency of stimulus presentation. These experiments

provided a special insight on the underlying processes of habituation.

Conclusion

Habituation is one of the simplest forms of nonassociative learning, it is found in all animal species, and it is a highly complex yet essential process of the evolution of learning. It has been demonstrated that underlying processes as interstimulus interval, stimulus generalization, and discrimination, and spontaneous recovery are interconnected and influence the occurrence and maintenance of habituation.

Half-Siblings in Human Evolutionary History

Definition

Half-siblings are either sired by the same father (paternal half-siblings) or born by the same mother (maternal half-siblings), but not both.

Introduction

In altricial species, such as primates, maternal half-siblings and full-siblings live usually in the proximity of each other and are raised up by the same mother. In contrast, the relation between paternal half-siblings is much less tight. The outcome of this difference in terms of social interactions, such as cooperation, aggression, and agonistic behavior, has been studied extensively in many mammalian species. Most research studying human behavioral ecology and the role of kin network, however, focused on full-siblings only. The current knowledge about the mating behavior of *Homo sapiens* and extinct *Homo* species suggests that this form of relatedness had always been present during the evolutionary history of the genus. Therefore, studying the interactions between half-siblings is expected to contribute significantly to our understanding of how resources are allocated between, and how support is given to, human individuals with different degrees of genetic relatedness.

Relation of Half-Siblings

Though the degree of genetic relatedness is the same, a distinction has to be made between maternal and paternal half-siblings. The relation of siblings within the two types is qualitatively different: on average, maternal half-siblings exhibit more interactions with each other, compared to paternal half-siblings (e.g., Pollet 2007; Tanskanen and Danielsbacka 2014). The main reason for this is that after a couple splits up, the children usually stay with the mother, so children from a new relationship grow up with the mother's other children. The shared family environment is an influential determinant of the half-siblings' relation (Pollet 2007).

Half-siblings – just as full-siblings – could either compete for resources (social, emotional, material, etc.) or provide resources to each other or both. Both types of relation can be explained within the frameworks of evolutionary theories, such as: (1) kin selection, (2) parent–offspring conflict, and (3) parental investment theory.

Siblings as Rivals

From an evolutionary point of view, the rivalization between siblings can be explained by kin selection (Hamilton 1964) and parent–offspring conflict (Trivers 1974). Trivers assumed that competition among full-siblings is less intense than among half-siblings. The results of empirical research, however, are contradictory (Pollet 2007; Tanskanen and Danielsbacka 2014; Salmon and Hehman 2015; Tanskanen et al. 2016).

In their study, Tanskanen et al. (2016) compared older (62–67 years) and younger (21–50 years) siblings. They proposed that the fact that they lean on the resources of the very same providers puts more strain on the relation of full-siblings. In general, the older generation showed less conflicts. Members of the younger generation had indeed more conflicts with full-siblings than with half-siblings. They also had more conflicts with maternal half-siblings than paternal ones, just like the older generation. However, the older full-siblings in the sample reported an increased likelihood of having conflicts with full-siblings over paternal half-siblings only, but not over maternal ones. The data were also controlled for emotional closeness, contact frequencies, and other demographic and socioeconomic family variables. This suggests that these within-family relations might be more successfully explained within the frames of the parental investment, rather than the inclusive fitness theory.

Siblings as Resources

Studies inspired by the kin selection theory yielded confirmatory data in the case of resource allocation. It was suggested that individuals will invest more in full-siblings than in half-siblings or step siblings (Emlen 1997). This view received support from Jankowiak and Diderich (2000), who found that half-siblings displayed significantly lower solidarity in a polygamous Mormon community in the USA. Solidarity was expressed in monetary gifts, requests to babysit, feelings of closeness, favoritism, and attendance at birthday and wedding celebrations. This happened despite

a strong cultural ideology for equal treatment of half-siblings.

Half-Siblings and Sexual Selection

In *The Mating Mind* Miller (2001) suggested that the mating pattern of the human ancestors in the Pleistocene might be best described as *serial monogamy*. This is similar to what is observed in extant hunter-gatherer communities. Exclusively monogamous pairs are formed for a couple of years and may split up either because of the death of one party or because of deserting. Then, new relations could be formed. On average, 3 months with regular copulations is necessary for conception. Therefore, in a relation which lasted for several years, one baby was likely to be born in every 2–5 years. Just like in most of the recent human societies, the major part of the costs of rearing a child was inflicted on the ancient hominid females. After the couples split up, this was even more the case.

Because of the serial monogamy, it is likely that the mating behavior of hominid females with one or more dependent offspring was combined with their parental behavior. Miller suggested that males hardly had any chance to court childless females. Hence, the main question was not whether a female has any children; her attractiveness and other reproductively important qualities were more of a concern. Sexual competition between females was, therefore, competition between mothers. It was proposed that mothers in the Pleistocene paid attention to how their children judged the prospective sexual partner. So the mothers' choice was influenced by the children's choice. Therefore, the courting of hominid males was directed partly on the offspring of the potential female sexual partner. An inevitable but somewhat surprising consequence of the children's preference was that through influencing their mother's choice, they influenced sexual selection and the genetic constitution of their younger half-siblings.

Conclusion

The kin network might have been much more complex during human evolutionary history than

it is often suggested by the traditional view of families in Western societies. “Patchwork” families of nowadays may stand closer to what was common in the evolutionary past. As the number of such families is increasing, and the relations between full- and half-siblings are getting more complicated, and eventually stressful, the reconsideration of the view of a “normal” human family is warranted both from a scientific and a therapeutic perspective.

Definition

According to Hamilton’s rule, the cost of an investment must be less than the benefit weighted by the genetic relatedness of the investor and recipient. Based on the condition “all else being equal,” individuals are predicted to invest more in closely genetically related kin compared to more distantly related kin or non-kin.

Introduction

William D. Hamilton (1964) formulated a rule that defined the conditions under which

altruism can evolve and spread in sexually breeding populations. Altruism refers to a behavior that decreases the fitness of the actor while increasing the fitness of another individual (West et al. 2011).

The Rule

Hamilton argued that in addition to the parent–offspring relation, other relatives who share a common descent carry identical copies of the same alleles (Mock 2011). Therefore, individuals can spread their own genes (inclusive fitness) not only by reproducing themselves (direct fitness) but also by supporting their relatives' reproduction (indirect fitness), even at the expense of their own direct reproductive success. Hamilton's rule, a mathematical formula of the above-described inclusive fitness theory, specifies the conditions under which altruistic behavior spreads in a population. The simplistic version of the rule can be formulated as follows:

$$Br > C$$

In the equation, B refers to the benefits of an investment, and C refers to the costs of the altruistic act. Benefits and costs are measured in terms of the investor's inclusive fitness. The coefficient *r* refers to the genetic relatedness between individuals, indicating the probability that the investor and recipient have an identical allele at a random locus by common descent (Salmon and Shackelford 2011). In theory, the degree of relatedness may vary between 0 and 1. For instance, among humans the degree of relatedness is 1 with monozygotic twins; 0.5 with a biological child and sibling; 0.25 with a half-sibling, grandchild, niece, nephew, aunt, and uncle; 0.125 with a great-grandchild and first cousin; 0.0625 with a first cousin once removed; 0.0313 with a second cousin; etc. The coefficient *r* mediates the benefit–cost ratio, and the greater the *r*, the easier the benefits exceed the costs. Hence, all other things being equal, the level of altruistic acts between individuals should correspond to the degree of their genetic relatedness.

Conclusion

According to Hamilton's rule, for the “altruistic gene” to be selected for and spread in a population, the fitness benefits weighted by the degree of relatedness must exceed the fitness costs of altruistic behavior. By contrast, if the altruistic gene decreases the inclusive fitness of individuals, it will be selected against by natural selection. Hamilton's rule is a simple but elegant equation that defines the circumstances in which altruism can evolve. Hamilton's rule also explains and predicts the variation in the level of altruistic behavior among kin.

Definition

Hamilton's rule predicts that individuals will be more likely to support closer kin altruistically, and thus more likely to get support from closer kin (Hamilton 1964). This refers to a biological law that defines whether an animal is going to participate in altruistic activity that does not appear to benefit their own well-being. The Hamilton law, named after the evolutionary English biologist W.D. Hamilton, says an animal will only engage in altruistic behavior if the indirect benefits it derives from such behavior are greater than the direct reproductive costs it entails. For example, when an animal shares similar genes with another animal requiring support, it is likely to demonstrate altruism. This has led many biologists to believe that at the gene level altruism could be simply selfish behavior.

Introduction

W.D. Hamilton in 1964 implemented the most famous law in evolutionary biology. He proposed a concept in two back-to-back papers and derived from it a law that we now know as Hamilton's rule. The rule states the selection favors altruistic conduct if the recipient's benefits times the relationship between actor and recipient outweigh the actor's costs. This captured both a qualitative perspective – genes can make people do things that are bad for that particular person, but good for copying the

gene in other people – and an elegant, intuitive, and easy quantification of that phenomenon.

Both the rule of Hamilton and the notion of “inclusive fitness,” which the rule suggests is maximized through evolution, have become standard material for both theoretically and empirically inclined biologists since. As is usual for a pioneering article, indications came that this is a key indication for outsiders as well. The paper contains almost half as many quotes as Darwin's (1859) “On the Origin of Species” and is one of the key ingredients in Richard Dawkins' (1976) “The Selfish Gene” and is one of the books that anybody with a general interest in science wants to read. Hamilton's law is not only a historic development but also the subject of a controversy. Karlin and Matessi (1983) and Matessi and Karlin (1984, 1986) also proposed in the early 1980s that not all evolutionary scenarios lead to a maximization of inclusive fitness, but those papers did not receive sufficient coverage to make it into the collective memory of evolutionary biology.

A renewed criticism of the generality of inclusive fitness has emerged in the last 7 years, the most notable of which was articulated in a paper by Martin Nowak, Corina Tarnita, and E.O. Wilson. Wilson. The latest debate on the generality of inclusive fitness does not yet display any signs of convergence and positions range from “nearly never holds the law of Hamilton” (Nowak et al. 2010) to “Inclusive fitness is as general as the genetic theory of natural selection itself” (Abbot 2009).

Hamilton's Rule

In the mid-1960s British evolutionary biologist William D. Hamilton offered the main insight for understanding the nature of self-sacrificing behavior. He argued that natural selection favors genetic success, not reproductive success per se, and that individuals should carry to future generations copies of their genes. Genes are transferred from direct parentage (rearing offspring and grand offspring) and aiding the reproduction of close relatives (such as nieces and nephews), a phenomenon known as “inclusive fitness” or “kin selection.”

Hamilton developed a theorem, now called Hamilton's law, which defines the conditions under which reproductive altruism develops: $r \times B > C$, where B is the gain (in number of offspring equivalents) gained by the beneficiary of altruism C is the cost (in number of offspring equivalents) sustained by the donor when participating in altruistic behavior and r is the genetic relation of the alt. Relatedness is the likelihood that the potential beneficiary of the altruistic behavior shares a gene in the potential altruist. Altruism can develop in a population if a potential donor of assistance can more than compensate for the loss of C offspring by adding a fraction r of its genes to population B offspring. For example, a female lion with a well-nourished cub gains inclusive fitness by nursing a hungry cub of a full sister because the profit to her sister ($B =$ one offspring who would otherwise die) more than compensates for the loss to herself ($C =$ about one quarter of an offspring), because her own, nonstarving cub's survival probability is only slightly reduced. If the mean genetic association (i.e., " r ") between two sisters is 0.5, so according to Hamilton's law (0.5×1) > 0.25 . Basically, altruism genes spread by encouraging help to replicate themselves.

Based to this view, popularized by the British zoologist Richard Dawkins, from a gene-selection viewpoint, the most acceptable way of understanding natural selection is as expressed in Hamilton's law. Genes that are best able to direct the species that carry them for successful transmission should survive and proliferate over generations. A description of the role of a specific action will also provide how the action encourages the performance of the genes underlying the behavior. Obviously, since an animal's actions almost always encourages genetic success by helping the animal survive and spread its genes, conduct research usually addresses the survival and reproductive value of the behavior.

Hamilton's Rule and Genetic Relatedness

Hamilton showed mathematically that, because other members of a population that share one's genes, a gene may also increase its evolutionary

success by indirectly encouraging the reproduction and survival of other people who also carry that gene. This is alternatively known "kin theory," "kin selection theory," or "inclusive fitness theory." The most obvious group of these individuals is close genetic families, and the application of inclusive fitness theory is often approached more straightforwardly by the narrower kin selection theory where these are concerned.

In addition to reciprocal altruism, Hamilton's theory is considered one of the two main reasons for the evolution of social behaviors in human organisms and a significant contribution to the field of sociobiology, which holds that all behaviors can be determined by genes and can therefore be passed on to future generations and can be selected as the organism evolves.

If there is a "altruism gene" (or gene complex) that affects the behavior of an organism to help and protect the relatives and their offspring, this behavior also tends to increase the proportion of the altruism gene in the population, as the families are inclined to share genes with the altruist because of common descent. In formal terms, if such a complex of genes occurs, Hamilton's rule defines the selective criteria for such a trait to increase the frequency in the population (in terms of cost, gain, and relatedness). Hamilton noted that inclusive fitness theory by itself does not assume that these altruistic behaviors will automatically evolve as an incentive or context for interaction among individuals is a more primary and necessary requirement in order for any social interaction to occur in the first place. "Altruistic or selfish acts are possible only when a suitable social object is available, as Hamilton puts it. In this sense behaviors are conditional from the outset" (Hamilton 1987, 420). In other words, while the inclusive theory of fitness specifies a set of conditions required for the evolution of altruistic traits, it does not prescribe a sufficient condition for their evolution in any species. More primary essential requirements include the presence, as described above, of gene complexes for altruistic traits in gene pool and in particular that, as Hamilton noted, "an acceptable social object is available."

Though presented in seemingly anthropomorphic terms, these concepts refer to all living

organisms and can explain the evolution of innate and acquired behaviors across a wide variety of species like insects, small mammals, or humans.

The ground squirrel from Belding offers an example. The ground squirrel is giving an alarm call warning its local group of a predator's presence. It gives away its own location by emitting the alarm, putting itself in further danger. However, in the process, the squirrel will defend its relatives within the local community (as well as the rest of the group). Consequently, if the effect of the trait influencing the alarm call typically protects the other squirrels in the immediate area, it will result in more copies of the alarm call trait being passed on in the next generation than the squirrel could leave by reproducing itself. In such a scenario, natural selection tends to increase the characteristic that influences giving the alarm call, provided that the gene(s) predisposing to the alarm call are included in a sufficient portion of the shared genes. (Mateo 1996)

Synalpheus regalis, a eusocial shrimp, is also an illustration of an organism whose social traits meet the set of criteria of inclusive fitness. The bigger defenders safeguard the colony's young teenagers from outsiders. The genes will continue to be passed on to succeeding generations, by ensuring the longevity of the young (Duffy et al. 2002).

Inclusive fitness is more universal than strict kin selection, allowing the shared genes to be of the same by descent. Inclusive fitness is not confined to cases affecting kin.

Application of Hamilton's Rule

Hamilton suggested that inclusive fitness provide a basis for the evolution of altruism in the sense of sociobiology. He believed this would lead to natural selection preferring species that are behaving in ways that correlate with optimizing their inclusive fitness. If a gene (or gene complex) that causes altruistic behavior has copies of itself in

others, helping others survive will ensure the genes are passed on.

Gardner et al. (2007) suggest that Hamilton's rule can be applied to multilocus models, but that it should be done at the point of interpreting theory, rather than the starting point of investigation. They propose that one should "use traditional population genetics, game theory, or other methodologies to derive a condition when selection favors the social character of interest and then use the law of Hamilton as an aid to conceptualize this outcome."

This insight has significantly extended population genetics, the genetic theory of natural selection and the Modern Synthesis, because it shows that natural selection of any gene depends on the effects of the gene, or lack of effects, on the direct fitness (number of offspring) of the copy bearers themselves. In terms of fitness, specific individuals are not sealed off from each other and traditional "individual selection" is, in the end, gene selection. All higher rates of organization, such as genomes, multicellular organisms, and populations, emerge from significant evolutionary transformations that are conditional on cooperating genes seeking a correlation of inclusive interest in fitness in bringing them about (Queller 2000).

Hamilton's rule offers a clear but powerful formalization of inclusive fitness theory (Grafen 1982). This states that a gene for any social change shall be selected if the sum of indirect fitness (rb) and direct fitness (c) exceeds zero, where r is the relatedness of the social actor and beneficiary and where c and b are the changes introduced about by social action in the number of offspring of the actor and the receiver, respectively. From the rule of Hamilton follow the well-known conditions for the four possible forms of social action defined by the signs of c and b , which include cooperation or mutual benefit (+, +), altruism (−, +), selfishness (+, −), and spite (−, −) (West et al. 2007). Specifically, in its most celebrated application, Hamilton's rule puts that altruism (net loss of direct fitness) is selected if $rb - c > 0$. Through defining this condition the

inclusive theory of fitness solved the altruism problem (Dawkins 1976).

The theory provides the best present basis for a unified understanding of social evolution because of its foundation in fundamental theory, its incorporation of the four types of social action and its universal taxonomic scope (Lehmann and Keller 2006). For example, it allows for a common understanding of conflicts between family groups and intragenomic conflicts (Haig 1997). This offers an overview of the biological structure itself as applied to the main transitions.

Proof for the inclusive theory of fitness is extensive, diverse, and growing. Nevertheless, there are relatively few clear empirical tests of Hamilton's law in natural populations. Hamilton's law states that any social activity can occur only under certain configurations of r , b , and c values. Factors that produce the required r , b , and c values inside natural populations create the conditions for social evolution. Variation in such values may then trigger social evolution in the sense of making the difference between whether or not social behavior undergoes selection (given the correct genetic variation). For instance, Hamilton's rule shows that positive relationships are a sufficient prerequisite for altruism evolution, and that altruism develops quite easily when b is high and c is low. So the identification of factors affecting the relative values of b and c gives insight into the causes of altruism for a specified relatedness structure (Korb and Heinze 2008).

Significance of Hamilton's Rule

First, Hamilton's rule introduces the gene's eye view of natural selection, noting that the important aspect for a gene to be evolutionarily successful is that it tends to leave more copies of itself to future generations regardless of the fitness effects experienced by individuals. This gives him a theoretical point of entry into the altruism problem and places the research within a systematic, population-genetic context.

Second, Hamilton's rule goes on to point out that, even after decreasing the reproductive fitness of the altruist, a gene encoding altruism may leave more replicas of itself in the future if the recipient also carries replicas of the altruist genes. This pinpoints, qualitatively, the selective benefit of the origins of altruism.

Third, being quantitative and using the vocabulary of "concentration" and "dilution," Hamilton states that it is the "regression" in the recipient of the altruistic genotype that defines how well the recipient transmits the genes of the altruist. He points out that Sewall Wright's correlation coefficient of relationship will well estimate this regression coefficient: that is, one-half for full siblings, one-quarter for half-siblings, and so on, in typical scenarios. This regression method to relatedness tests genetic similarity with respect to the average population, rather than in absolute terms, and it is in this sense that we can only be compared to our siblings by half despite sharing 99% of our genes with chimpanzees.

Fourthly, Hamilton puts together these observations into a single inequality, defining the required and sufficient condition for the gene to be favored by natural selection: $k > 1/r$, where k refers to the recipient's fitness gain ratio and the actor's fitness cost and r refers to the degree of relatedness. This basic finding now forms the cornerstone of social evolution theory and is referred to as "Hamilton's Rule" in its various forms" (Charnov 1977).

Fifth, by putting aside genes and paying attention to individual species, Hamilton derives from the evolutionary process a moral law, noting that "an animal operating on this theory would sacrifice its life if it could save more than two friends, but not less" (p. 355). This reflects a profound shake-up in Darwinian understanding, as it demonstrates that natural selection does not need to lead individuals to act as though they were trying to maximize their personal reproductive success and that, in certain circumstances at least, they will value their kin's lives.

Sixth, Hamilton clarifies that, in addition to nepotistic behavior toward known relatives,

natural selection will favor even indiscriminate altruism, such as birds' alarm cries, because adjacent individuals appear to be genetically related in viscous populations.

Hamilton's rule predicts that, all else being equal, individuals will invest more in their closely related relatives compared to their distantly related relatives.

Introduction

Inclusive fitness theory (Hamilton 1964) argues that individuals can spread their genes in future generations (inclusive fitness) by investing in the reproduction of their relatives (indirect fitness) in addition to reproducing themselves (direct fitness). Hamilton's rule is an equation of the above-described theory and can be described as follows: $Br > C$. In the equation, B stands for benefits and C refers to the costs, which are both measured in terms of reproductive success. The coefficient r represents the genetic relatedness between the investor and the recipient, indicating the probability that these individuals have an identical allele by common descent at a random locus (Salmon and Shackelford 2011). According to Hamilton's rule, the benefits of an

investment, weighted by the degree of relatedness, should exceed its costs. The theory has been investigated especially in nonhuman populations and empirical results have provided extensive support for the validity of Hamilton's rule in many species, such as eusocial insects, birds, primates, and many other mammals (Hepper 2011).

Hamilton's Rule and Human Populations

The benefits and costs of investments are difficult to measure because they are defined in terms of the overall reproductive success of an individual. Therefore, research on humans typically focuses on the genetic relatedness of individuals, which is the more measurable parameter of Hamilton's rule. On average, the degree of relatedness is 0.5 with parents, children and full-siblings, 0.25 with half-siblings, grandparents, grandchildren, nieces, nephews, aunts, and uncles, and finally 0.125 with great-grandparents, great-grandchildren, and first cousins. According to Hamilton's rule, all other things being robust, the investment between individuals should correspond to the degree of genetic relatedness.

The prediction is relatively well supported by ethnographic, experimental and self-report-based studies, which have shown that people typically invest more in their close relatives than their distant ones and, in general, the investments among kin or the willingness to invest reflects the patterns of their genetic relatedness (Burnstein 2005; Madsen et al. 2007). For instance, individuals are more willing to make sacrifices for the benefit of their siblings than their cousins and, respectively, individuals are closer with and provide more support to their full-siblings than their half-siblings (Neyer and Lang 2003; Pollet and Hoben 2011). Moreover, twin studies have shown that genetically identical monozygotic twin-pairs have higher levels of closeness and cooperation than dizygotic twins, whose relatedness is equivalent to full-siblings (Segal et al. 2007).

Conclusion

Hamilton's rule is widely applied in evolutionary studies. Nonetheless, it has also been criticized. The universal applicability of inclusive fitness theory was questioned in a recently published article by Nowak et al. (2010). In the following debate, almost 150 scholars stated that the critics had ignored an extensive amount of empirical studies that has accumulated over several decades and provide strong evidence for Hamilton's rule (Abbot et al. 2011). Overall, Hamilton's rule can provide a prediction and an explanation for kin altruism and it has gained extensive support from empirical studies.

Hamilton's rule is that an altruistic behavior can be selected for in a population under the circumstances that

1. The behavior is heritable (variance explained by genetic difference).
2. The gene underlying it provides a benefit to those who share that gene by common descent that is higher than the cost exerted, multiplied by the coefficient of relatedness.

This is usually simplified to $rB - C > 0$. In this formulation r is the relatedness coefficient between actor and beneficiary of behavior; B is the reproductive benefit provided to the recipient;

and C is the cost to the actor in terms of direct reproduction.

Introduction

The term “paradigm shift” should come with a health warning. Hamilton's rule, formalizing inclusive fitness, is one of those very few developments in science that genuinely deserves the accolade. Inclusive fitness is a central, axiomatic concept in evolutionary biology. Darwin's discoveries, concerning descent with modification from common ancestry directed by natural selection, were the result of years of painstaking observation and the synthesis of vast amounts of empirical data. Hamilton's rule is an extension of Darwin's insight, based on pure deductive reasoning as laid out in (Hamilton 1964) and further developed in papers of equal mathematical sophistication (e.g., Price 1972).

While the complexities of these original papers are rarely directly engaged with, the take-home message seems simple: Namely, that altruistic behavior can be selected for just in case that the benefit bestowed on the recipient (B) multiplied by the coefficient of relatedness between actor and recipient (r) minus the cost to actor (C) is greater than zero.

This is typically expressed as $rB - C < 0$.

Rarely has such a deceptively simple formulation had such profound consequences or provoked such large misconceptions and fights over interpretation. It has been argued that the rule as it stands is too simple to permit simple predictions on the basis of it (Frank 1998). Whether or not this is true, it has been tempting for scholars to rush to predictions based on it, perhaps in a version of physics envy. The upshot of this haste can then be that, following a supposed failure of Hamilton's rule to apply, scholars seek for other explanations for the source of a social behavior. In this vein it is worth emphasizing that there are a large number of things that Hamilton's rule does not imply and does not apply to – much though it may appear to.

Why does all this matter? It is not hyperbole to say that Hamilton's rule explains the otherwise miraculous. Miracles are, strictly speaking, things

that cannot be explained by appeal to natural laws. Darwin's insight explains how the world appears to be designed but without needing a designer. Hamilton's extension of Darwin's insight is no less momentous. It explains how moral behavior – which at its bedrock – requires the capacity to benefit others at a net cost to oneself (in other words, true altruism) can come into the world without a divinity to underwrite it.

Throughout history, humans have typically sought for supernatural explanations for the way that the universe contains both beauty and goodness. As Kant famously put it “Two things awe me most, the *starry sky* above me and the *moral law* within me.” Darwin's discoveries showed us that no designer was needed to create functionality and in the process reminded us that not all functionality was beautiful. Hamilton's rule unites all of nature in terms of how genuine altruism – a crucial social behavior – can exist at all without supernatural interference. In the process he similarly showed us that our intuitions about what is truly good cannot be relied on. Of course, this mathematical extension of evolution by natural selection has far more implications than simply that it is the most general formulation of natural selection yet devised.

Useful Terms

Adaptation: A trait that improves fitness – defined in terms of representation of genes in the next generation. Since Darwin and the modern synthesis, the only non-supernatural force that explains the appearance of design in this fashion is natural selection, although other forces (such as drift) can explain differential representation of genes.

Altruism: A behavior that imposes a cost on the actor and gives a benefit to the recipient. The word is usually applied to behaviors, but any trait could be altruistic – such as a physical trait that acts to benefit others at a cost to the user like a honey-bee's sacrificial sting.

Gene: The basic unit of selection. Whatever has the requisite properties of longevity, fecundity, and fidelity is a gene in the sense needed for evolutionary biology. Since the double-helix

nature of DNA has been uncovered (which has those three required properties), this has become the focus of research. However, interesting complexities such as the various kinds of interactions between genes make judgements that rely on a single “gene for x” potentially misleading. A useful way to think of genes for evolutionary biology purposes is as a catalyst whose catalyzing reactions influence its representation in the next generation (Dawkins 1976; Haig 1997).

Green beards: A putative tightly aligned property linking genes to phenotype that would allow them to recognize one another directly. It is controversial whether any genes do this, but no one claims that they do in the case of humans. However, humans do possess adaptations allowing them to recognize kin at better-than-chance levels.

Group selection: There are a number of meanings for this term, and not all are mutually consistent. The original use of the term, by Wynne-Edwards, to refer to voluntary limitation of fitness-producing behaviors so as to benefit the group has fallen out of favor as being shown to suffer from being fatally vulnerable to selfish invaders. While other uses do persist, there is to date no additional explanatory power that has been shown to be dependent on modeling social behavior in this way, rather than in terms of existing mechanisms such as inclusive fitness and mutualism. Group selection in the way precisely defined by Price (1972) can exist but only in extreme situations that do not pertain to human beings (such as groups budding and reproducing faster than their constituent elements do). That a group persists or expands is not itself an instance of group selection because the group is not, in this case, the unit of selection. Humans have a number of adaptations to groupishness, however, and these are important.

Heritability: The proportion of variance in a trait accounted for by genetic factors. It is important to note that heritability is not a fixed property. For example, as shared environments become more similar, then heritability increases. Heritability is sometimes confused with “genetic determinism” which is a largely meaningless phrase. The development of human heads can be safely said to be encoded in genes. The actual possession

of a head has a heritability of 0, because variance in the number of heads possessed by a specific human (0 or 1) will be entirely explicable in terms of environmental factors.

Inclusive fitness: Individuals can affect the transmission of their genes into the next generation either directly (their own reproduction) or indirectly (that of relatives). Inclusive fitness is an extension of Darwin's principle of evolution by natural selection so as to include social behaviors – indirect as well as direct benefits. It is inclusive fitness that Darwinian individuals can be assumed to maximize – making it the most generally applicable model for explaining adaptation yet formulated. Inclusive fitness can be measured through measuring the effect on offspring in general (direct and indirect) multiplied by the degree of relatedness. As such it is foundational and true by deduction once one accepts that evolution is through differential survival of genes in the gene pool. Attempts to disprove it are thus misguided, unless one first attempts to disprove the concept of fitness or the concept of genes. Hamilton's rule for inclusive fitness is often simplified to $rB - C > 0$, where r is the coefficient of relatedness, B is the benefit in terms of fitness, and C is the cost to the actor.

Kin selection: A term coined by Maynard Smith (1964) to explain the indirect fitness benefits that accrue from aiding kin reproduction and to distinguish this from group selection. In one sense kin selection refers to relatedness due to common descent. However, a broader use of the term refers to the degree of shared genes at particular loci – whether or not these happened to come from shared ancestry. However, given that green-beard effects (where genes can recognize copies of themselves) are likely to be rare, the differences between these uses are unlikely to matter much in humans. Hamilton does not use the term in his writings. Inclusive fitness (unlike kin selection) does not require actual kinship, just genetically non-random altruism (Hamilton 1975). This could occur through situations of comparatively low dispersal, for example.

Mutualism: Behaviors that provide fitness benefits (not necessarily equal) to both actors and

recipients. It is easy to mistake mutualistic behaviors for altruistic ones.

Relatedness: Although this is commonly thought to refer to shared genes, this is a simplification with consequences. A much better definition is to put relatedness in terms of the degree of genetic similarity between individuals related to the average background shared genetic similarity. See Box 1 (taken from West et al. 2011 and used with permission) for a more complete description.

Selfish: Behaviors that benefit the actor but impose a cost on the recipient.

Social behavior: Any behavior that has consequences for other individuals (Hamilton 1964). Mere presence may have consequences but it is not a behavior, per se. There are four types of consequence that can occur: altruistic, mutual, selfish, and spiteful.

Spiteful: Behaviors that impose costs on both recipient and actor. One of the strengths of Hamilton's (1970) formulation of social behaviors is its successful prediction of spiteful behaviors in cases where relatedness coefficients are negative.

Implications of Hamilton's Rule

Good theory both explains and predicts. It explains what we see and frames what kinds of questions we can ask of our observations. And, it makes (one hopes) surprising predictions about things that we might see and the things that, despite persistent search, we don't see. The more surprising the prediction, the more confident we are of the theory if it is confirmed. Darwinian evolution by natural selection explains the appearance of design in the natural world and places constraints on the sorts of traits that can exist by limiting the ways that they can come to exist. For example, Darwin could famously predict the existence of a particular kind of moth and its traits prior to its discovery, based on observations of a deep flower with nectar at its base.

Hamilton's rule makes similar surprising predictions and offers constraints on the sorts of social behaviors that can evolve. Its predictions are somewhat more complex to follow than

natural selection alone, however. The rule also makes predictions, but often not the ones attributed to it.

Inclusive fitness implies that organisms can be assumed to be acting so as to maximize their average lifetime fitness (even if individuals may deviate from this). Hamilton's extension of the Darwinian insight was to realize that this included not just the fitness of the individual themselves but also of their relatives. Social behavior involves more than one entity, of course. For ease let's call them an actor and a recipient. Either one, both, or neither can benefit from the interaction. This gives us four possibilities. If both benefit, this is mutualism. If neither benefits, this is spite. If the actor gains at the expense of the recipient, then they are truly selfish (in the technical sense of the word – they may or may not have selfish motives), whereas if the actor loses out but the recipient benefits, this is altruism (West et al. 2007). Once again, "altruistic" here means what it means in a technical biological sense. For everyday usage behaviors that are mutualisms (like both parents giving loving care to a child) might be felt to be altruistic when they are mutually beneficial. It is important not to be misled (by our natural tendency to be hypervigilant for our fellow humans' potential to be exploiting us) into thinking that these behaviors are somehow not really altruistic.

Questions That Biology Can Answer

Tinbergen (1963) helpfully defined the four types of biological questions that can be asked of a trait.

1. How does the trait contribute to fitness? (Evolutionary question.)
2. How does it function? (Mechanistic question.)
3. How does the trait develop? (Ontogenic question.)
4. How did the trait evolve? (Phylogenetic question.)

There is resemblance to Aristotle's four causes (material, formal, efficient, and final) with some scholars insisting that final causes

(teleology) correspond to the evolutionary explanation of a trait, and, possibly, Darwin himself may have flirted with this idea. However, teleology is end directed and evolutionary fitness is something that can only be seen in retrospect. Other than as a shorthand (i.e., organisms behave as if they are trying to maximize their fitness), the resemblance of evolutionary causation to teleology is misleading. Organisms are driven neither by an inner elan vital nor pulled by an external divine plan.

A useful general distinction following from Tinbergen (1963) is that ultimate answers are given to "why" questions, whereas proximate answers are given to "how" questions. Thus, in answer to a question about how eyes develop, a proximate answer might look at the development of eyes and ask questions such as "do neonates see color?" On the other hand, a question that asked "why do humans discriminate red and green" might make reference to our phylogenetic history and how the ability of our ancestors to discriminate ripe fruits from unripe ones increased their fitness. These would be ultimate questions.

Information and Price's Formulation of Altruism

The general application of game theory to evolutionary problems begins with the work of Smith and Price (1973) which showed how limited conflict between animals could be modeled without assuming some benefit to the species model. These insights depended in turn on Price's (1995 posthumous) formulation of Hamilton's rule. Here he realized that any useful mathematical definition of selection is needed to exclude "psychological factors of preferences and decision making" (p. 389).

This is important for a number of reasons, but one of them is that human beings – hypervigilant as they are to signs of possible fakery and betrayal in acts of apparent altruism – can be led astray by the notion that all altruism is somehow not real – by which they usually mean that the appropriate feelings associated with it may be absent in a

particular case. It may well have made a lot of evolutionary sense for our ancestors to test one another in the group for the presence or absence of particular moral sentiments. Indeed, we likely still do this in the form of gossip and similar behaviors. However, the proximate moral emotions of, for instance, empathy or shame, which mediate social behaviors, are not to be confused with the ultimate causes of how the gene underlying altruistic behaviors might be selected for by evolution.

Price (1995) makes an explicit analogy with how Hartley's (1928) definition of information, which made no reference to meaningfulness, was foundational to Shannon's (1948) insights into information theory. Hartley's (1928) definition of a practical measure of information was in terms of the logarithm of the number of possible symbol sequences. It is a striking fact, not lost on contemporary physicists, that this definition of information:

$$W = K \log m$$

(where W is the speed of transmission of information, K is a constant – to be empirically determined – and m is the range of voltage levels to choose from in the signaling system) Has so much in common with Ludwig Boltzmann's formulation of entropy

$$S = k_B \log W$$

(where S is the entropy of an ideal gas, k_B is Boltzmann's constant – an empirically determined number – and W is the number of microstates in that system).

The fact that energy and information can be put in terms of one another should alert scholars to the fact that the information referred to here does not require psychological meaning. This is important because many might otherwise assume that information requires some sort of irreducible semantic content – e.g., a mind that understands it – and it does not. In the same way, altruism (and aggression for that matter) can be modeled without any necessary ascription of proximate mechanisms by which they are manifested (such as loving feelings).

Genes, Selfish, and Otherwise

Genes can be helpfully thought of as catalysts whose catalyzing reactions affect their own representation in the next generation (Haig 1997). Another way to think of this is that they are as replicators that build vehicles through which they interact with the world, including one another (Dawkins 1999).

Game theory has become central to modeling these complex interactions of vehicles, providing testable and often surprising predictions (Smith and Price 1973). Gene frequency can be held in various kinds of dynamic equilibrium – helpfully referred to as evolutionarily stable strategies (ESS). This is a term borrowed from game theory to describe a set of strategies adopted by actors in a population that is stable. By “stable” it is meant that an invading (and rare) alternative strategy cannot invade and become dominant.

To a first approximation, an individual's gene's success is synonymous with her own. However, this isn't necessarily true when the fitness of relatives who share particular genes by common descent is factored in, and this is when Hamilton's (1964) insight comes into play. At this point a suite of possibilities for modeling and predicting behaviors opens up. Of course, analysis may not stop there. As Haig (1997) has pointed out, the genes may well be in conflict with one another at the level of expression within the individual as well. Indeed the latter provides a powerful test of how powerful the “selfish-gene” model really is (Dawkins 1976). To illustrate this consider the conditions of Angelman and Prader-Willi syndromes – both of which are usually considered as developmental abnormalities.

Unless genes are taken to be “selfish,” i.e., that they seek representation in the next generation even at the (possible) expense of their hosts, then a number of phenomena are inexplicable. A good example would be maternal/paternal drives for gene expression – genomic imprinting. Here, some proximate mechanism (typically methylation) causes some genes to prosper (be expressed) at the expense of others. Some genes know if they are derived from the father or the mother. A classic example would be genes on

chromosome 15 which code for the growth of the hypothalamus (Buiting et al. 1995). The father’s genes would benefit – i.e., maximize their representation – from an offspring which demands a lot from the mother, and the genes from his line try to force expression at the expense of the mother’s genes. At the same time, her gene’s interests (and her own) would be served by hedging her bets and not investing all in one highly demanding offspring.

Normally the conflict of these genes is held in dynamic tension – neither set winning out. However, the evidence that they reached this impasse through conflict lies in the conditions that (rarely) result if one set does happen to win out over the other. If the father’s genes win, then the baby develops Angelman syndrome (and is highly demanding), whereas if the mother’s win, Prader-Willi syndrome (also known as “happy puppet syndrome” for the relative undemandingness of the baby) is the result. If the fight for expression was silenced, then the offspring would be perfectly viable (Moore and Haig 1991). Therefore, the existence of the syndromes (which occur when the mechanisms are not in dynamic equilibrium) constitute evidence for selfish gene theory. They are the classic “signs of a struggle” that detectives see when they enter a crime scene; nothing else explains the syndromes in question. Note that these are not cooperative strategies because the more efficient ones (where both sides drop their weapons) are not evolutionarily stable strategies.

However, these examples are not per se social interactions, and at the level Hamilton’s rule operates, it is social interactions that are the normal focus of attention.

Cooperation and the Major Biological Transitions

It might be thought that evolution by natural selection implies universal conflict. It is true that, without a struggle for resources, there is nothing that counts as outcompeting others. However, the means of achieving this is frequently cooperative in nature. Selfishness of genes does not imply that

they cannot cooperate in many ways to achieve their goals. Cooperation is ubiquitous in nature. One way to see this is in terms of the eight major transitions that have occurred, each increasing the level of complexity and requiring a cooperative mechanism to do so (Smith and Szathmary 1997).

(1) Replicating molecules	=> Populations of joined molecules
(2) Independent replicators	=> Chromosomes
(3) RNA (gene and enzyme)	=> DNA and protein (genetic code)
(4) Prokaryotes	=> Eukaryotes (cells with nucleus and organelles)
(5) Asexual clones	=> Sexual reproduction
(6) Protists	=> Multicellular organisms with organs
(7) Solitary individuals	=> Colonies with sterile castes
(8) Primate societies	=> Human societies with language

Some might argue that cultural evolution also belongs in this line as the next step, but the majority view is that cultural evolution represents a separate process rather than a biological transition per se (West et al. 2011).

Direct and Indirect Fitness

Fisher (1930) made a crucial distinction between direct and indirect fitness. To increase direct fitness is to increase the representation of the actor’s genes in the next generation. It is also possible to have fitness modulated by the behaviors of neighbors. For a variety of obvious reasons, neighbors are more likely to be kin and this is indirect fitness.

Relatedness

Organisms have traits, and those traits can be quantified. The trait (phenotype) can be meaningfully separated into the heritable component and environmental component. Natural selection acts upon genes and changes the average value of the phenotypic quantity of interest in populations (not individuals) as Fisher (1930) showed. This is how

increases in fitness are defined. Furthermore, Fisher (1930) usefully separated such fitness increases into direct and indirect effects – the latter including improving the fitness of kin (see Fig. 1).

One of Hamilton's key insights was to realize that shared-gene underlying altruism could exist linearly as well as vertically in a population. "There is nothing special about the parent-offspring relationship except its close degree and a certain fundamental asymmetry" (Hamilton 1964, pp. 1–2). In Hamilton (1970) kinship by common descent can be calculated from shared genealogy. Subsequently it was appreciated that the direction of selection for social behaviors could be driven by appropriate statistical associations between individuals (Hamilton 1972; Price 1970).

Hamilton's early work takes an expressly population genetic approach – for example, he showed that the net effect of allele frequency on

related individuals can be expressed in terms of the fitness effects on those partners in relation to their degree of relatedness. This is exactly what $rB - C > 0$ implies. Later work (Queller 1992) showed that this is a special case of a more general model of covariant traits in a socially linked population. This later work fits Hamilton's insights into a quantitative genetics model but should not be seen as superseding these insights – rather as extending them to even further generalizability.

The "r" refers to the probability that a particular allele is shared through common descent. It does not imply anything about the proportion of shared genes in common. Humans share over 99 % of their genes – r measures the greater similarity between relatives above the background similarity between members of the same species.

An example of r: Let us assume the frequency of a particular allele in humans is 0.9. If I have a brother, then he is related to me with a coefficient of relatedness of 0.5. For us as a pair of siblings,

Hamilton's Rule and Theoretical Implications,

Fig. 1 Inclusive fitness is the sum of direct and indirect fitness (Hamilton 1964). Social behaviors affect the reproductive success of self and others. The impact of the actor's behavior (*yellow hands*) on its reproductive success (*yellow offspring*) is the direct fitness effect. The impact of the actor's behavior (*yellow hands*) on the reproductive success of social partners (*blue offspring*), weighted by the relatedness of the actor to the recipient, is the indirect fitness effect. In particular, inclusive fitness does not include all of the reproductive success of relatives (*blue*

offspring), only that which is due to the behavior of the actor (*yellow hands*). Also, inclusive fitness does not include all of the reproductive success of the actor (*yellow offspring*), only that which is due to its own behavior (*yellow hands*; adapted from West et al. 2007). A key feature of inclusive fitness is that, as defined, it describes the components of reproductive success which an actor can influence and therefore which they could be appearing to maximize (Reprinted from West et al. (2011) with permission)

half the time my brother will get the allele in question from the same parental chromosome as I did and half the time from the other parental chromosome. Therefore the probability of him sharing the particular allele with me is $\frac{1+0.9}{2} = 0.95$. This is (intuitively) halfway between the background frequency of the allele and 1. It is possible that using the concept of gene frequency rather than fitness might forestall confusion.

Families and Tribes

For parents to invest in offspring is species typical across taxa, with the types of investment varying according to a host of factors. In humans it might be thought that, as human children are so labor-intensive, investment would be total and preclude other behaviors. However, there is plenty of scope for the interests of parents and offspring to diverge somewhat. Parent-offspring conflict is a theme developed by Trivers (1974). The patterns of investment are predicted to alter in accordance with the possibility of investing in further offspring and viability of the offspring in question among other things.

Altruism toward families, both immediate and extended, requires some mechanisms, and Hamilton proposed that both kin-recognition mechanisms and the natural result of populations with a high viscosity could be the local means by which these occur. The various forms of potential markers of kin recognition are a rich field of enquiry. It could involve such markers as facial features, smell, dialects, skin tone, and proximate markers of tribal allegiance. Viscous populations are those where dispersal is sufficiently low that proximate mechanisms that treat mere proximity as sufficient to cue kinship can be selected for. These will form part of what Dawkins (1999) calls an extended phenotype, and, once again, this is a rich source of potential enquiry.

It is even possible that otherwise hard to explain behaviors such as homosexual preference (as distinct from homosexual behaviors which are far more common across taxa) might be explained in terms of inclusive fitness. If so-called helpers at the nest effects could occur with humans with the

benefits conferred offsetting the costs involved, then this could explain the development and preference of such behaviors. No one has, to date, convincingly shown this to happen without other assumptions being built in to the models.

There is a natural consequence of favoring one's kin and tribe and that is potential disfavoring of those who are not kin or who might be threats to resources. Indeed, this is what we find. Not only is in-group favoritism species typical in humans, but there is also a marked Cinderella effect – with those who are not one's offspring – but are still making demands on one's parental care, being at increased risk of neglect or even violence (Daly and Wilson 1998).

Strong Reciprocity and Economic Games

Humans do not just help one another; they also punish those that do not help. This calls for an explanation because said punishment is costly. Evidence for these moral dispositions – such as pride, envy, spite, shame, helpfulness, and similar – can be found cross-culturally and even sometimes in prelinguistic neonates favoring puppets who display such tendencies. A large literature – too large to fully review here – involving economic games, has developed to demonstrate these tendencies across human populations (see West et al. 2011, for an extended discussion of economic games in this context). This tendency to punish transgressors and free riders in a community is sometimes referred to as “strong reciprocity.”

It is especially important in considering models of such behavior to distinguish proximate mechanisms, such as feelings of moral outrage at transgressors, from ultimate causes for the selection of such mechanisms, i.e., how they might have contributed to fitness (Mayr 1961). Such selection may be in terms of altruism *sensu stricto*, but it is at least as likely to be evidence of a mutualistic system. While it is important that we can model human behavior in laboratory, or quasi-laboratory settings, care must be taken with conclusions that appear to be challenging Hamilton's rule. They are not; any more than the fancifully irreducibly

complex systems beloved of the creationists are a challenge to evolution by natural selection. While there may appear to be an elegant symmetry between maximizing utility functions and maximizing inclusive fitness, it doesn't follow that the world acts this way. Often, Hamilton's rule is not being addressed at all.

One of the consistent findings from experimental psychology is that participants do not see themselves as isolated laboratory creatures but as full human beings who also live outside of laboratories and might meet the recipients of their generosity or cruelty at some point – whatever an experimenter might insist. Thus, the use of so-called one-shot games (especially where it appears that people are more cooperative than expected) must be carefully considered. The experimenter might see them as one shot. It does not follow that this is how the participant sees them. Natural selection works by generating proximate mechanisms that maximize inclusive fitness on average. The fact that such systems can be made to misfire does not invalidate natural selection. No one would argue that the existence of pornography undermines sexual selection, just because humans can be fooled by it into generating nonreproductive behaviors.

As an example, consider the data on ultimatum games. These are where one actor makes an offer and the other participant can choose to accept or reject it. It turns out that a robust finding is that people make larger offers that standard economic theory would predict, and it could be argued that this supports a contention that humans are notably more cooperative than utility-maximizing (taken as a proxy for inclusive fitness maximizing) theory would allow for. However, as West et al. (2011) point out, the data could equally well support a rather more depressing conclusion – namely that humans are notably more antisocial (and know it) than we previously wished. If humans have evolved to recognize that other humans are especially spiteful and vicious, then they might expect low offers to be punished. Thus the surprising behavior would be the rejection of lower offers, and we could (equally) conclude that humans are more punitive than previously thought.

It is possible that scholars have been misled by the word “selfish” in the title of Dawkins (1976) work into mistaking the maximizing of representation of genes (ultimate causation) with selfish motives (proximate motivation). Expecting selfish behavior, scholars perhaps have been pleasantly surprised to find that humans are not, in fact selfish. But selfish gene theory never predicted that they were, and showing that they are not doesn't undermine the model of the selfishness of genes.

Even more common than ultimatum games is the prisoner's dilemma. This is an experimental economic situation involving a payoff matrix that allows researchers to model interactions of cooperation and defection. It is common to find it assumed that the prisoner's dilemma has proved that in one-shot games the strategy of defection (selfishness even to the point of spite) should be maximized but that cooperative tit-for-tat exchanges will thereafter defeat all other strategies in iterated interactions. Frank (1998) provides a sophisticated set of ways to model such interactions in a way that does justice to the complexities – modeling the biology of actual interactions rather than assuming that the world must be fitted, procrustean style, to the most elegant mathematical model. It turns out that neither of these assumptions is correct.

Group Selection and Selection for Groupishness

For a variety of interesting reasons, the term “group selection” has become almost synonymous with culture and morality in some quarters. In part, this confusion is that selfish genes make selfish people (and that therefore some special, extragenetic mechanism is required to make them social), but there is more to the issue than this.

Organisms cooperate, often at a cost to themselves. How, given the famous Darwinian struggle for survival, is this possible? In the 1950s and 1960s, many social behaviors were explained in terms of benefits conferred on individuals (e.g., Tinbergen 1951; Lorenz 1966). Group selection

arguments, sometimes even arguments in terms of the benefit to the species as a whole, were frequently invoked. In Wynne-Edwards (1962) proposed that organisms would voluntarily reduce their own fitness – for example, by limiting their own reproduction – so that the wider group could survive. One can still hear arguments of this kind in general circulation, although more rarely among scholars.

Both logic and empiricism were fatal to these sorts of group selection arguments, however. In terms of logic, it was reasoned that any such adaptations would be ruthlessly outcompeted by intruders that exploited them. Then, when the data were explored, it was found that the sort of self-limiting behaviors predicted could be shown to not occur.

There are other forms of group selection, including ones where the unit of selection is itself the group rather than the gene or includes the gene as well in so-called multi-level selection. All scholars agree that this sort of group selection can occur; indeed the covariance equations of Price (1972) could be expanded on one side of the equation without any limit so as to encompass any unit of selection that is desired. However, such expansion comes at a cost that the effect of selection decreases exponentially with such expansion. What this means in practice is that if groups were to bud and reproduce faster than their elements do, then group selection would overtake individual selection. In the absence of this, the effects of group selection are going to be vanishingly small, and no one has convincingly shown that this could occur with human beings.

Advocates of group selection in relation to humans tend to emphasize helping rather than, for example, genocide. But genocide and other activities like suicidal sacrifice for a military cause would potentially provide some of the strongest evidence for group selection, and in humans it is certainly well attested in our histories. Critics of inclusive fitness models are sometimes explicit that they believe that such selection dooms us to being ultimately selfish (Wilson and Sober 1998). But, “selfish” here is equivocal. Humans are very interested in the motives of one another. For example, we are intensely interested

in whether someone's motives can be trusted. To say that someone is selfish is tantamount to saying that, at crucial moments, they cannot be relied upon. But the selfishness of genes – their blind replication at the expense of others (unless those other genes produce mutual benefit) – must not be confused with selfish motives. Genes have no motives.

What Hamilton's rule explains is not that all so-called altruistic motives are at heart a sham. On the contrary, it explains how genuine empathy, self-sacrifice, and love can exist without supernatural intervention. By analogy, if someone were to see a brain scan of a loved one and noted that their ventral-tegmental area was firing strongly in response to a stimulus of them, would they conclude that “love was not real” because they could see its activity in the brain? They would be foolish if they did – because what they have just seen is actual evidence of just what a real thing love is.

Philosophers have struggled for millennia to try to make sense of our sense of morality. Where could it have come from? Is it god? Is it reason? Is morality somehow part of the fabric of the universe? What Hamilton's rule demonstrates is that some aspects of morality – those that give rise to empathy, for example – are indeed part of the fabric of the universe. This is not the whole of morality, of course. And Hamilton's rule certainly provides no guidance (or possibly only provides bad guidance) on a human's actual conduct. However, it provides a non-supernatural source for our proximate social feelings toward one another.

When something persistently reoccurs in human thought, it's likely not simply a misunderstanding but revealing of underlying cognitive architecture. As Lewis Wolpert famously put it, science is profoundly unnatural. We have only been performing science (rather than mere data collection about local regularities) in recent times. The conclusions of science are typically counter-intuitive and require a record of testing and failures to build up gradually. Scientific conclusions often jar with our sensibilities.

For instance, various forms of Lamarckism (inheritance of acquired characteristics) keep cropping up in each generation perhaps because humans, as obligate investors in their children,

probably cannot quite bring themselves to believe that the minute details of what they do as parents – unless they do some truly ghastly things – are normally swamped by the effects of genes. Similarly, perhaps it is the case that group selection keeps recurring as a plausible source of human moral behavior because it feels intuitively evident that we often suppress our needs for the sake of the group.

Indeed, some prominent scholars have made such introspection a major pillar of their arguments for group selection (Wilson and Sober 1998). But intuition and introspection are very misleading here. Given our species' long-documented capacity to have major sections of cognitive architecture opaque to others, it would be premature indeed to consider introspection as final. As Marvin Minsky memorably put it in an interview with Ken Campbell, "all parts of your mind are treating the other parts like tiny robots and finding ways to trick them." There is absolutely no reason to treat our inner emotions about the "good of the group" as anything more than an effective way to get ourselves to advertise ourselves as selfless members of the said group. Indeed, given that the most effective way to fool others is to sincerely believe it oneself, we have very strong reasons to be deeply suspected of introspections in this particular area most of all.

An important implication raised by Hamilton (1975) is that altruism in semi-isolated groups depends on the migration rates rather than the size of the groups. This is a rather surprising finding, but Hamilton showed that the interrelatedness of the groups will gradually tend toward the level of siblinghood if there is, for example, just one migrant per two generations.

Misconceptions About Inclusive Fitness

As well as stating what Hamilton's rule is, it is important to state what it is not. Misconceptions about inclusive fitness abound, leading to a number of attempts to rectify this in the theoretical literature (Dawkins 1979; Griffin et al. 2002; Park

2007; West et al. 2011). Some of the most common of these (that particularly matter in relation to human beings) are:

1. That cooperation is altruistic. This misconception may partly be due to the fact that humans have such exquisitely sensitive reactions to the potential cheaters and traitors in a group. This likely results in the notion that a suggestion that a behavior is somehow not really altruistic (because the actor also benefited) becomes conflated with the idea that the cooperation is itself not genuine. In fact, many cases that are described in the literature as "altruistic" are in fact mutualistic; both actor and recipient benefit from them. It may be better to call "reciprocal altruism" by other names to emphasize this fact (West et al. 2011). Reciprocity (Trivers 1971) can be direct or indirect (mediated, e.g., through reputation in humans), but it is not altruistic, in the strict sense required by Hamilton's rule, if both parties increase fitness through the behaviors. There are a multitude of mechanisms for enforcing cooperation and these have been found across taxa. The most common is simply punishing transgressors (West et al. 2011). None of these mechanisms require Hamilton's rule or require elaborate new types of explanations to be able to explain their occurrence (although they may well require sophisticated and sensitive modeling, of course).
2. That relatedness is merely about shared genes. This is incorrect. Only genes that influence behavior (through possible altruism) can fall under the kind of selection that Hamilton's rule describes. For instance, two clones who had no altruistic genes would not aid one another simply because they were genetically identical. Nor is altruism somehow proportional to shared genes. Humans and mustard grass share 15 % of their genes but do not show any measurable degree of altruism toward one another. As stated clearly by Krebs (1987), "The reason why relatedness is important. . .the coefficient of relatedness between two individuals is equivalent to the probability that they share the gene for altruism, not because they

share a high proportion of other non-altruistic genes" (p. 93).

One consequence of this is that simplistic models of individuals doling out lumps of altruism in proportion to the degree of relatedness of family members are very unlikely to be empirically verified. Generational asymmetries in investment and reproductive value are likely to be important variables, for instance.

3. That there is something special about siblinghood, cousinhood, or other similar kin relationships. This is also untrue. One of Hamilton's insights was to appreciate that parent-offspring relatedness was only one way in which relatedness might matter. In a diploid species (such as humans), each offspring has a 50 % chance (ignoring complications) of inheriting a specific altruistic gene. So as long as the benefits bestowed on the offspring outweighed the costs incurred in fitness by the parent multiplied by 50 % (the coefficient of relatedness), the gene could be selected for. Indeed, non-kin who happened to share a cooperative gene could act altruistically, in principle. While it is unlikely that this happens in humans, limited dispersal patterns and viscous populations can frequently mean that groups of humans who are apparently not close kin are still highly related to one another.
4. That kin selection is group selection. Selection for groupishness is not the same as group selection. There is no space here to explore all the variety of possible meanings of the term "group selection," but some have been discussed above. It is worth noting that evolutionary biologists in general accept the fact that group adaptations (which is one of the meanings attached to the term) can only occur in very specific circumstances that do not apply to humans such as in communities of clones or in situations with no within-group competition. Many evolutionary biologists would argue that putting things in terms of group selection adds nothing in terms of explanation but carries a potential for confusion (see West et al. 2011 for an extended discussion).
5. That kin selection requires the ability of genes to recognize one another. This putative property is sometimes referred to as a "green-beard" ability (Dawkins 1976). If the gene that underlays an altruistic behavior also pleiotropically produced both visible markers (e.g., the eponymous green beards) and the preference for such markers, then the genes could aid each other more directly. This appears to be very rare in nature. However, kin discrimination can occur through a variety of proximate cues. The most obvious of these is a shared early environment. In birds this would typically be a nest, but there is plenty of evidence (such as the famous Westermarck effect that prevents siblings' sexual interest in one another) of humans' assuming (not necessarily consciously) that those they grew up with are close kin. Other likely sources of interest for humans might include the ability of fathers to discriminate likely offspring, patterns of investment that reflect degrees of paternity uncertainty, and the role of infanticide and natal neglect (see West et al. 2011 supplementary material for an extended discussion of the research in this field).
6. That animals, and humans prior to arithmetical ability, need to be able to consciously calculate relatedness (Sahlins 1976) for Hamilton's rule to apply. No conscious calculations are required here; any more than spiders are required to be able to perform Weyrauch's formula of load bearing to be able to build their webs. Mathematics may be used to model and predict behaviors, but not necessarily the mechanisms by which those behaviors occur.
7. That altruistic behavior is too complex to be captured by a single gene and that therefore there cannot be a "gene for altruism." This is misleading. Fisher (1930) noted that phenotypically neutral genes were likely to be very rare in practice. Behaviors grow out of complex interactions of genes, not one single "gene for X." By way of example, a behavior that involves the feeding of chicks in the nest probably relies on a complex interplay of many genes working through proximate rules such as "feed whatever is in your nest, has a large patch of yellow, and is making a noise." This

rule can be exploited by, e.g., a cuckoo in a reed warbler nest. However, a mutant gene that caused the reed warbler to treat its younger siblings as its offspring (say) would be an altruistic gene in the strict sense; it reduces the older reed warbler's fitness but increases that of its siblings. Such a gene would not create the feeding behavior from nothing; it would build on existing behaviors (Dawkins 1979).

8. That Hamilton's rule predicts specific interactions between individuals. For example, it is not true (despite Haldane's famous quip) that humans regularly give their lives for two brothers or eight cousins. Neither does Hamilton's rule predict that they will (or should). Despite this, it is common to see Hamilton's rule presented in undergraduate textbooks as something that will predict specific altruistic acts (see Park 2007, for extended discussion and examples of this misconception occurring). Hamilton's rule describes the circumstances under which a particular altruistic gene can be selected for, not proximate instances of behavior.

Conclusion

Hamilton's rule (1964) is a foundational, axiomatic extension of Darwin's (1859) insights concerning how species develop through natural selection. Where Darwin (1859) explained the apparent miracle of design without recourse to the supernatural, Hamilton (1964) explained the underlying apparent miracle of morality – i.e., altruism – without recourse to anything other than the components of natural selection. This insight isn't the whole of moral behavior of course. Human morality also requires reason to, for example, extend thought and behavior in logically consistent terms. Hamilton's rule certainly does not itself provide a justification for behaviors. Indeed, inclusive fitness would seem to promote (say) nepotism, and this tendency is not a justification – rather the reverse.

One of the things that humans intent on building a better world would be wise to do is to pay

attention to the grain of human nature rather than be in denial of it. Humans are not slaves to their genes but their genes do keep culture on a leash, to echo E. O. Wilson's memorable phrase. Hamilton's rule delineates one of the most important ways in which this occurs. Does this make human morality some sort of mistake, as some people seem to fear? In short, do the nihilists (as H. P. Lovecraft joked) have a point when they say "The world is indeed comic, but the joke is on mankind." Not in the least. The recognition that our (proximate) moral sensibilities evolved in strict accordance with the known rules of biology means that they are real things.

More than that in principle, this realization gives us ways to identify and perhaps deal with those who do not share those proximate sensibilities. Those who lack empathy, for instance, are in principle just as disabled as those born without eyes. Biology is silent on the rational application of such moral sensibilities as shame, pride, and the desire to protect others, however. The rational application of these sensibilities in individual morality, or in the large-scale coordinations that politics requires, is a very human ability too and relies on our ability and need for reason and consistency. Only a highly simplistic moral philosophy would assume that feelings and sentiments alone were the whole of human ethics.

For biologists (and psychologists who accept that psychology must be at a bare minimum consilient with biology), then Hamilton's rule represents a powerful tool. As with all powerful tools, the potential can go both ways. Although it might seem daunting to face up to the challenges that the mathematical formulations require of us to model human behavior, it is also worth bearing in mind that human minds are a collection of complex kludges that evolved over millions of years in response to many conflicting pressures. The promise of an elegant predictive mathematical tool in the manner of the theoretical physicists is a tempting goal, though probably never attainable. That said, Hamilton's rule probably comes as close to being such a realization of the Ionian enchantment – the unification of all sciences through mathematics – as we are ever likely to get in behavioral science.

Definition

The Handicap Principle suggests that many aspects of animal morphology, behavior, and communication are best understood as *handicaps*.

A handicap reliably advertises an animal's quality because it signals that the organism is of sufficient quality to tolerate the burden the handicap places on it. Central to this principle is the idea that the costliness of the handicap ensures the reliability of the message being conveyed.

Introduction

Upon spotting African wild dogs (*Lycaon pictus*), Thomson's gazelles (*Gazella thomsoni*) will sometimes start *stotting* – repeatedly leaping up and down using all four legs. Instead of fleeing to safety, these gazelles call attention to themselves, squandering valuable time and energy. Why do they engage in such an ostensibly dangerous behavior, and how could it possibly be favored by natural selection? The answer lies in the handicap principle – one of the oddest and most counterintuitive theories in evolutionary biology.

The Logic of the Handicap Principle

The Handicap Principle suggests that a stotting gazelle is sending a message to its predator - and that this message is effective precisely *because* it is wasteful (Zahavi, 1975; Zahavi & Zahavi, 1997). The gazelle is advertising its physical fitness to persuade the predator to pursue a less physically fit gazelle instead. In essence, the gazelle is saying “look at how physically fit I am – I see you coming, but I’m so confident in my ability to outrun you that I can afford to waste time and energy in this otherwise pointless behavior. You would be better off chasing one of my less physically fit peers instead”. The key idea is that only physically fit gazelles can afford to engage in this wasteful display. Consequently, stotting is a reliable indicator of the gazelle's fitness. It is precisely the costliness of the display that guarantees the veracity of the message, rendering it an “honest signal”. And because the message is reliable, it behooves the predator to attend to the information it is receiving. Indeed, studies confirm that predators prefer to chase gazelles who stot weakly or do not stot at all – and they are more likely to succeed in the hunt when they go after a nonstotting gazelle than when they go after a

gazelle that stots (FitzGibbon and Fanshawe 1988).

The key claim of the handicap principle, then, is this: many features of animals – ranging from bodily markings to behavior and communication – are handicaps. These handicaps exist because they convey honest, reliable information about the animal bearing the handicap. It is the costliness of the trait that ensures the truthfulness of the message conveyed.

The peacock's tail provides a canonical example. It requires physiological resources to build and maintain, attracts the attention of predators, and hinders the peacock's ability to escape. From the point of view of natural selection, it seems costly and wasteful – a metabolically expensive burden that decreases the peacock's chances of escaping predation. So why do peacocks build such extravagant tails?

Many readers will know an initial answer: because peahens find it attractive. But *why* do peahens find such a wasteful burden attractive? The handicap principle's counterintuitive answer is that they like it *precisely because* it is a wasteful burden. Because it is so costly, only males of high quality can *afford* such a burden. As such, the size, color, and patterns on a peacock's plumage serve as reliable indicators of the male's underlying genetic quality. The peacock's tail thus provides reliable information about his physical fitness and genetic quality – key information for a peahen's mating decisions. This captures the central logic of the handicap principle: the costliness of the handicap ensures the honesty of the message.

Before we evaluate the theory on its scientific merits, considering other examples of the handicap principle may help bring the logic of the theory into relief and simultaneously offer a sense of its scope.

The Handicap Principle in Nonhuman Animals

Skylarks escaping from falcons sometimes sing in mid-flight (Cresswell 1994). Because singing requires oxygen and energy, only skylarks in the best physical condition can afford to sing while fleeing – it is a reliable signal to the falcon that this particular skylark is healthy and fit, and that the predator would do better to pursue one of the

skylark's weaker peers. And indeed, studies show that if a skylark sings during escape, the falcon often aborts the chase. But if the skylark does not sing, the falcon continues to pursue it, and often succeeds (Cresswell 1994). The handicap principle thus explains a behavior that would otherwise appear inexplicable.

Siamese fighting fish offer another illustration. When two such fish get into an altercation, they may flare their gill covers, holding them erect. This is a wasteful display – it needlessly surrenders partial use of the gills and thereby impairs respiration. Gill flaring is a signal to one's competitor that one is so formidable that victory is assured despite the handicap of partial respiration. Weaker, less formidable fish cannot afford to do this. Sure enough, when such a fight takes place, the fish that holds its gill covers erect for the longest period of time toward the end of the fight is most likely to be the victor (Simpson 1968).

The Handicap Principle in Humans

The logic of the handicap principle is not limited to any particular species and should theoretically apply with equal force to our own. Are there features of human morphology, psychology, or behavior that are best understood as handicaps?

One candidate is female preference for testosterone-dependent traits in men. Testosterone is a known immunosuppressant (e.g., Folstad and Karter 1992) and is one of the reasons why men are more susceptible than women to a range of diseases (Bouman et al. 2005) and die several years earlier than women, on average (Buss 2015). Like the peacock's tail, high levels of testosterone can be a heavy burden in terms of health and survival. As such, only high-quality males can afford to produce high levels of this immunosuppressant. The handicap principle suggests that one reason why women are attracted to testosterone-dependent features such as a deep voice, strong jawline, and high shoulder-to-hip ratio is that these traits are evidence that the male in question is of sufficient quality to be able to tolerate high levels of a harmful immunosuppressant. Just like the peacock, his ability to afford a heavy handicap is a reliable indicator of his

underlying genetic quality (Hamilton and Zuk 1982; Smith 1985).

Is the Theory Likely to Be Correct?

When Zahavi first proposed the handicap principle (1975), many scientists ridiculed the idea. Ethologist Richard Dawkins evaluated the idea unfavorably in his landmark work *The Selfish Gene*, and evolutionary biologist, geneticist, and game theorist John Maynard Smith published a mathematical model showing that the principle was unworkable (Smith 1976). The handicap principle met with much resistance in the scientific community.

With time, attitudes changed. Ethologist and evolutionary biologist Alan Grafen published a mathematical model demonstrating that, under more realistic assumptions than those of the previous model, the handicap principle could indeed work in natural populations (Grafen 1990). This turning point, in conjunction with the continued flow of empirical evidence emanating from the Zahavi research team, gradually changed the opinions of many scientists. The handicap principle now enjoys both a mathematical proof of concept and a wealth of empirical evidence. Some questions remain about the principle's scope – some thinkers regard it as an extremely wide-ranging theory, while others are more circumspect. But the remaining debates no longer center on the conceptual tenability or mathematical feasibility of the concept, and the theory is now well-regarded among evolutionists. Richard Dawkins went so far as to reverse his initial view, saying this in the 30th anniversary edition of *The Selfish Gene*: “If Grafen is correct – and I think he is – it is a result of considerable importance for the whole study of animal signals. It might even necessitate a radical change in our entire outlook on the evolution of behaviour, a radical change in our view of many of the issues discussed in [The Selfish Gene]” (Dawkins 2006, p. 313)

Evaluating the Theory on Its Scientific Merits

The handicap principle has several scientific strengths. First, the hypotheses that fall under its umbrella are eminently testable. Second, the theory is broad in scope, dealing with topics as diverse as mate selection, predator-prey

interactions, parent-offspring relationships, chemical communication, animal coloration, ritualized fighting, parasite-host coevolution, altruism, humans, social insects, and even social amoebas. Third, the theory unifies diverse, seemingly unrelated phenomena by pointing to a deeper logic that underlies their surface variability. Fourth, the theory is parsimonious, and while the biological processes involved can be complex, the underlying logic of the principle is clear and simple. And fifth, the theory has heuristic and predictive power, suggesting new avenues of exploration and making new predictions. For example, because the principle maintains that there must be a logical, nonarbitrary connection between the nature of a signal and the message it conveys, the theory enables one to deduce from the nature of a signal what message it conveys and vice versa.

Novel Hypotheses

We would like to end by advancing a few novel handicap hypotheses in humans. It has been argued that, since immune function may be inversely related to disgust, people may down-regulate their disgust in front of potential mates in order to convey a robust immune system (e.g., Al-Shawaf et al. 2015). Although it has not been framed as such, this is essentially a handicap hypothesis: individuals' decreased disgust exposes them to heightened risk of pathogens, thereby conveying reliable information about their health and immunity.

Second, we suggest that the pride display, which involves a raised chin, lifted arms, protruding chest, and exposed torso (Tracy and Matsumoto 2008), is also a handicap. The person showing pride in this manner is exposing himself to attack and making himself vulnerable. This cost is tolerable for formidable individuals but constitutes a heavier burden on weaker or less capable individuals. We suggest that pride displays therefore convey reliable information about the quality of the individual engaging in them.

Third, we suggest that the practice of fighting for the right to pay the bill in a restaurant (common in the Mediterranean, for example) is a manifestation of the handicap principle. Despite the surface-level variability between this cultural practice,

potlatch dinners in tribal environments, and conspicuous consumption in urban environments, they are all underlain by the same logic: people are attempting to publicly handicap themselves with a financial burden in order to reliably convey their socioeconomic standing to their peers.

These examples represent only a small subset of the many manifestations of the handicap principle detectable in modern cultures, ranging from golf handicaps through chess handicaps to blindfolded skateboarding. The idea is not that humans have evolved adaptations tailored to modern innovations like golf or skateboarding, of course, but rather that selection favored the evolution of psychological mechanisms designed to flexibly use local cultural cues as handicaps, thereby honestly advertising an individual's ability or quality.

Conclusion

The handicap principle suggests that most animal communication is honest and reliable. This honesty is guaranteed by the cost of the communication – the message is too costly to fake. In other words, the cost is prohibitive for liars but not for those who are telling the truth. For example, the investment required to build the peacock's brilliant plumage is manageable for a male of genuinely high quality, but prohibitively costly for a male lacking the relevant physiological and genetic resources. The costliness of the peacock's tail guarantees the reliability of the information it conveys.

Scientists initially rejected this idea but have generally come to accept it. Though strikingly counterintuitive at first, its underlying logic is sound, and it has the hallmarks of a good scientific theory: testable hypotheses, unifying explanatory ability, parsimony, broad scope, and heuristic and predictive power. It is buttressed by both mathematical and empirical support, and it changes the way we look at much of animal communication.

Definition

- (I) Cohesive social group that is constituted by one or few dominant individuals of one sex (usually males) and, respectively, two or more individuals of the other sex (usually females), and in which dominant individuals actively fight nonmember competitors for all or, at least, the vast majority of the copulations with the group members of the other sex.
- (II) The assembly of individuals of one sex (usually females) that is sexually monopolized by one or few individuals of the other sex (usually males).

Introduction

Polygyny (i.e., the mating combination in which one male is paired to two or more females) is found in different forms, including resource defense polygyny, female defense polygyny, scramble competition, and leks (Emlen and Oring 1977). In these mating systems, high-quality males acquire more than one mate because they are more successful than low-quality males in premating competition. However, this higher success is defined in different ways in each of these polygynous systems. In leks and scramble competition, high-quality males are more successful because they are more effective in finding and/or courting females, but they do not actively restrict the access of other males to females. There are situations, however, in which males do not only compete for finding and courting mates, but also defend females, directly (i.e., female defense polygyny) or indirectly (resource defense polygyny). If a mating system/social group is characterized by a male that prevents other males from accessing his breeding partners, this may be termed a *harem*. However, through the decades, the term *harem* has been applied to a variety of contexts, leading to a gamut of different definitions of the concept. The heterogeneous nature of the concept of *harem* is presented in the following sections.

The Different Applications of the Term *Harem*

In behavioral ecology studies with nonhuman species, the term *harem* is most commonly used to designate social groups and mating systems that comprise just one male and more than one female. Social groups of one male and at least two females are found, for example, in arachnids (Gonyleptidae harvestmen), crustaceans (isopod *Paracerceis sculpta*), insects (stone and tree wetas, and bark beetles), fishes (*Centropyge*, *Serranus*), *Agama* lizards, great reed warbler, pheasants, northern harriers, *Sacropteryx* bats, elephant seals, fur seals, geladas baboons, hamadryas baboons, gorillas, langurs, pronghorn antelopes, red howler monkeys, red deer, and zebras. In some of these organisms, the harems can be part of a larger grouping of individuals, such as baboon troops. However, for each sub-grouping inside the troop, there is a cohesive interaction between a specific male and two or more particular females, which characterizes, under this definition, a *harem* (Lancaster 1975).

In the examples mentioned above, once females are clustered in space and/or time, a set of males in the population can monopolize sexual partners and prevent other males from mating. For example, female pinnipeds (seals) concentrate on beaches during the reproductive season and, once they are clustered in an area during a specific period, high-quality males can monopolize them, becoming harem bulls that fight off other males. Female monopolization may be achieved by defending territories (e.g., fur seals) or by defending the females per se from the attempts of competing males (e.g., elephant seals), allowing the dominant male to enhance his fitness.

By naming as *harems* the groups formed by one male and more than one female, it is assumed that one male and two females form a harem. It is also common to describe *harems* as groups composed of one male and several (or many) females. Yet, some authors define as *harems* even the groups of one male and just one female, given the potential of the male to acquire additional mates during the same breeding season. Further

still, some authors also name as *harems* those groups composed by few males that, together, monopolize a larger number of females. These male coalitions are found, for example, in animals such as the chimpanzees, feral horses, lions, and the cichlid fish *Pelvicachromis pulcher*. This joint effort of males may allow the monopolization of females and the maintenance of a harem when there are too many females and/or the females disperse along extensive areas.

Harems can be classified into two categories. Seasonal harems may occur when females are highly synchronized with respect to their sexual receptivity, and their monopolization remains feasible (e.g., red deer, *Cervus elaphus*). And permanent harems may occur when there is little synchronization in the availability of breeding females, and males are forced to defend their partners constantly (e.g., hamadryas and gelada baboons) (Davies et al. 2012).

Lastly, the term *harem* can also be used to designate: (a) social groups in which females are the polygamist sex that monopolizes sexual partners (i.e., *polyandrous harems*; e.g., phalaropes and jacanas), (b) social groups in which an individual of one sex monopolizes conspecific hermaphrodites (e.g., some serranine fishes) (Leonard and Córdoba-Aguilar 2010), and (c) the set of individuals of the most numerous sex in a given social group (i.e., if a single male defends three females, these females can be named *his harem*).

Harems and Their Evolutionary Implications

When few individuals control access to mates, the intensity of sexual selection upon the controlling sex is large. In pinnipeds, for instance, a large male can control a harem with more than a hundred breeding females. Given that one single male controls all the females at his harem by ferociously displacing challengers, many males will remain unmated. Once few males copulate with several or dozens of females and other males gain few or no mates, there is intense sexual selection (i.e., nonrandom differences in mating success;

Kokko and Jennions 2008), and just a few males achieve high fitness.

The great variance in mating success between males tends to lead to the evolution of costly traits that favor males in male-male competition for the access to females. As discussed by Darwin (1871), this may lead to the development of extravagant secondary sexual traits in the non-limiting sex (males, usually). For instance, there are the great differences in size and aggressiveness between the sexes in pinnipeds and red deer. Red deer also presents great antlers, which are used in fights for access to mates. The development of antlers and the fact that several fights for harem control result in males with permanent wounds, such as broken legs or perforated organs (Davies et al. 2012), show that males can suffer extreme costs in highly polygynous systems.

Under the Shadow of Harem Masters

The great mating success of dominant males that hold harems contrasts with the mean mating success of males that do not possess a harem. Among the latter males, some will engage in alternative strategies to achieve some matings. In the isopod *Paracerceis sculpta*, while large males hold harems, and defend females from the attempts of challengers, small males use their low detectability (derived from their reduced size) to sneakily enter the harem and mate. Additionally, medium-sized males mimic the size and behavior of females, enter harems, and mate without being displaced by dominant males (Shuster and Wade 1991; Shuster and Wade 2003). Sneaking behavior occurs in several *taxa*, such as harvestmen, amphipods, decapods, elephant seals, and ungulates.

The existence of harems promotes conflicts between the sexes. These sexual conflicts of interests emerge because, in harems, some males can prevent others from accessing females, which may preclude females the opportunity to choose the identity and number of sexual partners that could maximize their fitness. Moreover, the sexual conflict may emerge in cases in which the dominant harem male kills unrelated offspring,

as has been recorded for lions. This happens when the male has recently acquired the harem, and he is assured that he is not the father of the young. This behavior guarantees that the male will not care for the young of a competitor and may bring the female to a fertile state sooner. However, from a female perspective, this behavior only represents a reduction in her reproductive success.

Controversies Regarding the Term

Given the constrain imposed by harems upon the maximization of female fitness, and the existence of male alternative strategies, it is not surprising that, despite the vigilance of the dominant harem male, various females do copulate with other males (e.g., blackbirds, seals, Gunninson's prairie dogs, *Hamadryas* baboons, and the cichlid *Pelvicachromis pulcher*). This leads to sperm competition and reduction of the dominant male's fitness. If dominant harem individuals are not able to secure the great majority of copulas, it could be argued that they are not monopolizing, *sensu stricto*, sexual partners.

It also has been pointed out that the term *harem* brings problems derived from an anthropomorphist approach of studying animal behavior. Early naturalists interpreted animal mating systems by relating them to some specific human social organizations, particularly the harems (Rowell 1991). However, despite the several slightly different definitions of *harem* in human contexts, the human harem encompasses important political and economic aspects that match no straight analogy in other animals' harems. In several human societies, the harem represents the political power that derives from the position occupied by a particular man in the social stratification. Moreover, in some ancient human harems, the dominant individual could turn his wives into exclusive sexual partners, once eunuch guards were employed to protect his harem. Thus, the harem owner was assured to father all the children of all the women in his harem. Given these differences between human and nonhuman harems and that anthropomorphism is not an exclusive problem of early naturalist, but also a mistake in which

current scientists may incur while studying non-human animals, it has been proposed the use of substitutes to the term *harem*. One such synonym that has been used is the term *one-male group* (Lancaster 1975).

Conclusion

The use of the term *harem* has a long history, while at the same time not having a consistent definition. Harems are a widespread form of social organization in animal reproductive systems. Among species, harems differ in the structure of group composition and in which sex is in the role of dominant individual. The variation among different species in aspects such as group composition is very likely one of the main causes for the lack of a consistent definition of what a *harem* means. Moreover, as the term was first coined to define a form of human social group, carrying human-specific context, it does not readily apply to the reproductive systems of other animals. Presently, there is little consensus as to the definition of the term *harem* and its applicability to different organisms.

Definition

In Sam Harris' (2010) book, *The Moral Landscape*, he argues that human values can be interpreted scientifically through the examination of what contributes to the well-being or suffering of conscious creatures.

Introduction

Neuroscientist and philosopher Sam Harris argues in his book, *The Moral Landscape: How Science Can Determine Human Values* (2010), that a scientific approach to morality will be able to establish objective truths about what is right and wrong in terms of what causes conscious human and nonhuman animals to thrive or suffer. Because conscious beings are governed by the laws of nature and are responsible for conceptions of moral values, he proposes that morality can be construed and developed as a natural science. In Harris' view, applying an empirical approach to morality is reasonable because "human well-being entirely depends on events in the world and on states of the human brain" (2010, p. 2). To make this case, Harris observes that experiences that cause human's varying degrees of happiness or pain tend to be evaluated similarly by people around the world. For example, there is likely to be universal agreement that a life in which one is afforded pleasure, freedom, and the basic needs for survival is preferable to a life in which one experiences fear, hunger, and physical and emotional pain on a regular basis. Thus, Harris surmises that there are objective, identifiable conditions that allow for more or less favorable experiences in life.

Overview of The Moral Landscape

Harris first establishes that verifiable accounts about organisms and their environments constitute scientific facts about natural phenomena (i.e., observable events discoverable by empirical study). By extension, Harris asserts that we have the capacity to use the scientific

method to determine facts, or high probabilities, about what will best serve to minimize the suffering of conscious creatures and maximize their success. These facts, Harris contends, should qualify as moral values, which he operationalizes as: "the set of attitudes, choices, and behaviors that potentially affect our well-being, as well as that of other conscious minds" (2010, p. 12).

Harris prudently clarifies that the science of morality he advances does not prescribe drawing from human nature to identify moral values. Specifically, he does not propose that what is natural is right (i.e., he does not claim that something is good because it is natural or bad because it is unnatural) or that we should model morality on basic human motives (e.g., mate acquisition, parenting, etc.). Harris further denounces religion and faith as determinants of morality, arguing that religious belief is frequently in direct contradiction with reason and is responsible for impediments to social progress and human welfare. Harris additionally rejects the doctrine of *moral relativism* (similar to *cultural relativism*), which contends that moral judgements espoused by groups from different cultures are all equally valid and moral in their specific contexts. Like religion and faith, Harris argues that relativism is an obstacle to the pursuit of determining and implementing universal human values. According to Harris, moral facts about the quality of human life revealed by empirical analysis will transcend culture, just as, he notes, physical and mental health do.

Importantly, Harris' proposed science of morality is not absolute or immutable. Because our understanding of human well-being will improve and evolve, he maintains that we should correspondingly revise our definition of what constitutes a moral value. Additionally, Harris recognizes that there may be various methods of increasing well-being or reducing suffering, but disagreements about the best routes to morality do not imply that we should revert to relativism. Overall, Harris' work aims to stimulate a discussion among scientists to establish a normative science of morality in hopes of promoting universal human values.

Conclusion

Many critics of Harris' *Moral Landscape* take issue with his proposal of applying scientific principles to morality and maintain that science and ethics are separate disciplines that should not intersect (e.g., Blackford 2010; Horgan 2010; Isaacson 2012; Jollimore 2010; Nagel 2010; Pigliucci 2011; Robinson 2010). Some of Harris' critics argue that he assumes that minimizing the suffering of conscious creatures should, in fact, be a moral value because science cannot itself determine what criterion are moral (e.g., Pigliucci 2011). However, Harris preemptively addressed this criticism in the final chapter of his book (2010), recognizing it as the key assumption of his argument. In a later response to his opponents, Harris (2011) pointed out that reason and science itself are necessarily founded upon presuppositions (e.g., respect for evidence, logical cohesion, valuing an understanding of the natural universe). According to Harris, if we aspire to act morally, then it is counterproductive to spend time arguing over these inherent assumptions and debating whether it is theoretically important to ask moral questions. Although scientific inquiry into morality may be a challenging endeavor, it does not follow that there are no answers to these questions. Notably, Harris holds that instead of searching for affirmative answers to what promotes the well-being of conscious beings, we ought to more rigorously pursue answers to the question of what causes them measurable suffering. He also suggests that we have reasonable ideas of what some of these immoral practices may include (e.g., enslavement, genocide, the denial of basic human rights).

Other reviews of *The Moral Landscape* are more positive and have offered constructive recommendations to further Harris' science of morality. In their review, Diller and Nuzzolilli (2012) call upon behavior analysts to support and advance an empirical approach to morality by employing behavior change techniques to encourage prosocial (i.e., moral) behavior. Wall and Shackelford (2011) present a largely favorable review of Harris' argument but observe that, while Harris indeed argues for respecting the

well-being of nonhuman creatures, he provides inadequate attention to issues of animal welfare (e.g., animal testing and the consumption of animals). Although a scientific system of morality is not currently attainable in practice, several academics are supportive of its pursuit (e.g., Diller and Nuzzolilli 2012; Wall and Shackelford 2011), including Richard Dawkins, Lawrence Krauss, and Steven Pinker, whose endorsements are printed on the book's dust jacket (Harris 2010).

Harsh Environments

Definition

Harsh environments are external conditions that present a heightened or unusual challenge to the fitness of individual organisms, the stability of populations and longevity of species, or even the robustness of ecological communities.

Introduction

Harsh environments are external conditions that are detrimental to survival for most forms of life. These conditions limit the growth, abundance, or

distribution of organisms and populations in an ecosystem. The challenges posed by such environments are typically conceived of as being abiotic in nature. Although by no means an exhaustive list, severe limitations of essential nutrients or vitamins, resources such as water or energy (in the form of heat or light), space or shelter, and extremes of temperature, pH, salinity, or altitude are all limiting factors that contribute to the harshness of an environment. Humans and many other organisms have nevertheless adapted to survive and even flourish in these conditions.

Disambiguating “Harshness”

An environment may be considered “harsh” for a variety of reasons. It is necessary to distinguish these senses of harshness since each may have substantially different effects on the ecological dynamics of a population or community and the evolutionary dynamics of a species. Two distinct but not necessarily exclusive general criteria for harshness can be captured by using the labels *abnormal* and *unpredictable*.

“Statistical abnormality” can be attributed to environments that exhibit extreme values of limiting abiotic factors that fall well beyond the average as calculated across all known species. This form of trans-specific extremeness is typically correlated with lower species diversity. Take, for instance, exposure to sunlight. One extreme value on the spectrum for this limiting factor is realized in habitats hidden well beneath the surface, such as caves and sewers. As well as being a valued source of energy for many species, light is a requirement for even the most basic forms of sightedness. The evolution, ontogenetic development, and maintenance of a complex adaptation like the eye are costly. In many cases, the fitness enhancement that comes with sightedness is well worth the cost. Even the most basic forms of vision, simple photoreceptors, often enable the organisms that have this capacity for detection to evade predators or snare prey that cast shadows, as well as reliably migrate to areas that receive greater or lesser amounts of sunlight and correlated resources. For species of cave-dwelling fish

(e.g., *Astyanax mexicanus*), however, there has been strong selection for the loss of functional eyes and thus blindness because of negligible light levels in their local environments (Cartwright et al. 2017). This is a harsh environment in the sense that relatively few extant species encounter or could survive in conditions where there are no immediate photosynthetic primary producers and no way for them to see.

It is precisely to statistically unusual environments that organisms commonly known as “extremophiles” have adapted (Archibald 2014). Although these are usually microbial life forms that thrive in geochemical or physical conditions that are typically too extreme for complex multicellular forms of life, examples can be found in all three domains of life (Rothschild and Mancinelli 2001). Perhaps, the best-known extremophiles compose a phylum of small invertebrates known as tardigrades (*Tardigrada*) or “water bears.” Species of this phylum can be found in almost every habitat on Earth. They can withstand temperatures ranging from -200°C to 151°C , a complete lack of water or oxygen, boiling alcohol, the low pressure of a vacuum or six times the highest pressures found in the deepest part of the oceans, and more than one thousand times the lethal dose of X-ray radiation for a human (Bordenstein 2019).

A subtly different sort of abnormally harsh environment is one that is unusual for the members of a species when viewed from an evolutionary perspective. A human example is informative in this context. The preference for and occasional overconsumption of fatty or sugary foods was likely adaptive for our hominid ancestors since opportunities to exploit such energy-dense resources were somewhat rare. Evolutionary precursors who exhibited trait variants for effectively exploiting these resources were on average more likely to survive and reproduce than those of our distant ancestors who exhibited less effective trait variants for doing so. Exploitative (i.e., gluttonous) foraging behavior and an enhanced ability to store energy in fat cells thus increased relative inclusive fitness in this “normal” environment for our ancestors, also known as the environment of evolutionary adaptedness, or the environment to which humans became adapted during the

Pleistocene. But in most modern societies, this behavioral strategy no longer maintains the fitness advantage that it once held.

To understand why this is so, it must be mentioned that many aspects of the metabolic control system are established early in fetal development. Among these are the craving for food, insulin sensitivity, and the number of fat-storing cells. Normal maternal constraints during pregnancy can generate an upper limit on how much nutrition a fetus can sense. These constraints have the effect of directing the fetus to anticipate an environment that is not quite as bountiful as the one its mother experiences. The developing fetus responds by exhibiting increased insulin resistance and allocating more resources to the development of fat cells than necessary. When energy-dense environments are rare, there is no problem with this response; it can be a useful strategy in cycles of feast and famine. However, energy-dense foods have been readily available in most developed countries since the agricultural revolution. Worse yet, many of the modern foods we consume are explicitly engineered to falsely exhibit the common cues for high energy density (e.g., saltiness without corresponding high protein content) and thereby trigger virtually uncontrollable cravings. The fetus is subsequently born into a modern environment teaming with such resources. Blood glucose levels rise when these foods are consumed, which results in heightened insulin levels. Due to increased insulin resistance, however, the process of restoring normal blood glucose levels becomes biased toward storage of fat rather than more immediate usage. The outcome, of course, is a situation in which obesity and metabolic disorder have become global epidemics. There is a severe mismatch between the environment of evolutionary adaptedness and our statistically normal but nevertheless “harsh” obesogenic environment (Gluckman et al. 2005).

The foregoing forms of harshness are due to statistical or evolutionary *abnormality*, which involve uncommon extremes of limiting abiotic factors or significant departure from the conditions historically associated with periods of adaptive evolution, respectively. An altogether different form harshness can come in the form of

environments that are unpredictable. Essential resources fluctuate in most environments. There are, for example, regular and thus highly predictable daily changes (e.g., light hours per day) as well as seasonal climatic variations (e.g., colder Fall/Winter temperatures giving way to a warmer Spring/Summer). The relative stability of fluctuations like these over a *geologic* timescale has granted species time to adapt to such conditions on an *evolutionary* timescale.

Predictable fluctuations in limiting factors are contrasted with what is called “environmental stochasticity” in the relevant scientific literature (Lande et al. 2003). Environmental stochasticity refers to *unpredictable* spatial or temporal fluctuations in environmental conditions. Notice that the inability of an organism to precisely predict a future state of the system is due to extrinsic ecological features. This should not come as a surprise. For, upon close inspection, most (if not all) natural habitats exhibit highly localized and effectively random spatiotemporal fluctuations in available resources. Given that there is insufficient time for finely tuned adaptive evolution, survival in such adverse spatially or temporally “patchy” conditions requires adopting a sub-optimal survival strategy (i.e., allocation of available resources). Since no attainable strategy can reliably make perfect predictions about the future, there will be a continuum of (suboptimal) strategic variation along which some strategies fare better than others.

Unpredictably harsh environments are often the background conditions against which constrained trade-offs in the strategic allocation of resources and the evolution of life history traits are examined (Stearns 1992). This is evinced in the theoretical contrast between the reproductive strategies known as *r* and *K*. For present purposes, it is worth noting that unstable or unpredictably harsh conditions generally lead to strong selection for a high fecundity, low investment strategy (*r*), the idea being that at least a few small and quick-to-mature offspring will survive in the face of high mortality due to environmental instability. Niche construction theory – wherein it is argued that organisms significantly modify their environments and

thereby influence selection pressures on some population of recipient organisms – takes the ability of organisms to manage (minimize) the harshness of the environmental conditions to be fundamental (Laland et al. 2014). And research on cooperation suggests that such behavior facilitates the colonization of harsh environments (Cornwallis et al. 2017), which in turn implicates harsh environments as an explanatory factor in the maintenance of altruistic behavior.

The point to note is that environmental harshness due to unpredictability does not involve uniform distribution of or prolonged exposure to statistically extreme and, thereby, unusual values of a limiting abiotic factor. Quite to the contrary, unpredictable environmental fluctuations can mirror the average (statistically normal) conditions present in *both* the environment of evolutionary adaptedness *and* current environments. This can happen when (i) the resources available to a population are distributed in a spatially non-uniform (i.e., “clumped” or “patchy”) way over a limited area, or (ii) there are irregular temporal fluctuations in the available amount of a resource within a population’s habitat. Some of the spatial parts or temporal stages of a habitat accordingly experience statistically extreme values of limiting resources. However, the quantitative influence that these locally extreme values have in the calculation of average (arithmetic mean) conditions for the habitat as a whole can be offset when there are enough complementary high/low values from other parts or stages of the habitat. The arithmetic mean value for a limiting factor in a habitat can, therefore, remain unchanged even as environmental variance in the availability of limiting resource, not to mention corresponding uncertainty regarding resource allocation, increases. Environmental stochasticity thus makes for a “normal” but nevertheless harsh environment insofar as it induces individuals to adopt allocation strategies that maximize actual fitness (especially the fitness component of survival) at the expense of expected fitness (maximum fecundity). Following Matthewson and Griffiths (2017), it might be prudent to label these unpredictably harsh conditions “inhospitable” rather than “abnormal.”

Conclusion

The Importance of Harsh Environments

The recognition and study of harsh environments is of vast importance to ecological and evolutionary theorizing. Simply identifying the range of values for limiting factors over which species can thrive is hugely informative. In astrobiology, for example, it is typically the capacities of extremophiles in harsh environments that bound the possibility space of our thinking about whether and where life is likely to be found. For a more “down-to-earth” illustration, we can turn to conservation biology. Human-induced climate change is an unprecedented threat to human and nonhuman life. One way to understand and possibly predict ecological and evolutionary dynamics in the age of dramatic climate change is to examine how organisms have already adapted to harsh environments, past (via paleontology) and present.

Health Benefits of Nature

Definition

Physical and mental well-being may be fostered by being in nature, viewing natural scenes, and bringing natural elements (e.g., indoor plants and natural light) into built environment.

Introduction

The work of several scholars in the area of human-environment relations confirms the notion that contact with nature may be beneficial for human health and well-being. This idea is very intuitive and is reflected in the fact that most people, regardless of their nationality or culture, prefer natural environments over urban environments (Parsons 1991) and that the majority of places that people consider favorite or restorative are natural places (Kaplan and Kaplan 1989). While the relation between contact with nature and human well-being may seem quite obvious and self-explanatory, there are many nuances to be taken into consideration.

In most studies, the effects of natural environments are compared to the effects of urban environments, which usually pose some specific health hazards for people, including pollution, crowding, sensory overstimulation, noise, etc. Natural environments may be beneficial in comparison just because they lack those exact sources of health risks. On the other hand, adverse effects of being in nature are rarely investigated since contemporary humans rarely face the same challenges that our ancestors had been exposed to during the most of our evolutionary past (e.g., encounters with predators, stress and injury from exposure to adverse environmental conditions, etc.). Thus, the scope of research on health benefits of nature is framed by the needs and lifestyle of contemporary humans, majority of which lives in urban environments with limited access to nature.

The most investigated benefits of contact with nature include enhancing people's ability to cope with stress and illness, fostering recovery from mental fatigue, and mood regulation.

Stress and Recovery

There is ample evidence that exposure to natural environments enhances the ability to cope with and recover from stress and recover from illness and injury.

One of the fundamental studies in this area of research found that patients with a natural view from their hospital room recovered faster, spent less time in hospital, had better evaluation from nurses, required fewer painkillers, and had less postoperative complications after gall bladder surgery compared with those who viewed an urban scene after the same surgery (Ulrich 1984). Subsequent studies explained the mechanism behind these effects: natural settings elicit a response that includes a component of the parasympathetic nervous system associated with the restoration of physical energy (Ulrich et al. 1991a).

Similar effects are found in other potentially stress-eliciting environments and situations. Access to nature in the workplace is related to lower levels of perceived job stress, higher levels of job satisfaction, and fewer reported illnesses and headaches (Kaplan and Kaplan 1989). Prison cell window views of nature are associated with a lower frequency of stress symptoms in inmates, including digestive illnesses and headaches (Moore 1981). Recovery from commuter stress in car drivers was quicker for participants who viewed nature-dominated drives than participants who viewed artifact-dominated drives, and the former also experienced greater immunization to subsequent stress (Parsons et al. 1998).

Attention Restoration

Kaplan and Kaplan described "restorative environments" as those settings that foster recovery from mental fatigue (Kaplan and Kaplan 1989) (Kaplan 1992a, Kaplan 1992b). The main four elements of every restorative environment according to them include fascination (an involuntary form of attention requiring effortless interest), a sense of being away (temporary escape from one's usual setting or situation), extent or scope (a sense of being part of a larger whole), and compatibility with an

individual's inclinations (opportunities provided by the setting and whether they satisfy the individual's purposes). Many natural environments and especially urban parks provide an opportunity for restorative experiences due to their ability to satisfy those four elements.

Even a view of nature may have restorative effects. In a study by Tennessen and Cimprich (1995) students who occupied dormitory rooms with natural views from their windows showed an increased capacity for directed attention when compared to students who occupied rooms with built views (views of buildings), so the authors concluded that views of nature may indeed be related to better attention restoration experiences.

Attention restoration effect of viewing natural scenes has been replicated in numerous studies since then, and some practical implications have been purposed both in prevention of mental health and in therapy of various disorders (e.g., attention deficit disorder).

Mood and Outlook on Life

A review of the literature on the psychological response to nature concluded that nature elicits feelings of pleasure, sustained attention or interest, and relaxed wakefulness and mitigates negative emotions, such as anger and anxiety (Rohde and Kendle 1994). It is noted that, in general, people have a more positive outlook on life and higher life satisfaction when in proximity to nature, particularly in urban areas (Kaplan and Kaplan 1989).

From Research to Practice

Environmental approach may be considered along with other health-promoting interventions in fostering and recovering human health and well-being. This approach as a preventive strategy may include both behavioral interventions, e.g., developing healthier habits (like going to nature frequently, tending a garden, keeping indoor plants and animals as pets), as well as design interventions in built environment (such as adding more greenery and water features into urban environment,

planning buildings with natural light, allowing employees to keep photographs of nature in offices, etc.). Recovery from various illnesses may be fostered through nature-based therapy like wilderness, horticultural, and animal-assisted therapy.

Conclusion

There is empirical evidence that beneficial effects of contact with nature for humans include fostering attention restoration, enhancing ability to cope with stress and illness, and mood regulation. Since various mental disorders are among leading contemporary health challenges, contact with nature may be included as preventative and restorative strategy in the domain of mental health and as an aid to recovery from physical illness.

A phenotypic trait that reflects underlying physiological health.

Introduction

Researchers have advanced a range of hypotheses to explain why individuals perceive some phenotypic traits as attractive. One such hypothesis is that these phenotypic traits act as cues that reveal valid information about the bearer's underlying physiological health. Choosing healthy long-term (or even short-term) mating partners confers obvious fitness benefits. Understanding precisely what aspects of health such traits reflect is not always straightforward. Modern medicine and abundant high calorie food (at least in Western diets) has likely weakened, obscured, or even modified ancestral relationships between health and some phenotypic traits. Further complexities arise from the breadth of states (such as current nutritional state, and disease burden) and traits (MHC heterozygosity and immunocompetence) that contribute to an individual's health.

The Evolution of Cues and Signals of Health

One important consideration is whether the phenotypic trait in question is a cue or a signal of health. Signals are traits that have evolved under selection pressures arising from others' – the receivers' – behavioral responses to the trait in question. Cues, on the other hand, are traits that correlate with physiological health in such a way that observers can extract reliable information, but have not evolved under selection pressure to communicate that information (Scott-Phillips 2008). It is frequently difficult to establish whether a trait is an evolved signal of health or simply a cue that correlates with health. For example, fluctuating facial asymmetry (random deviations from bilateral symmetry) are thought to reflect developmental perturbations, resulting from developmental stressors. Thus, high facial symmetry reflects few developmental perturbations and may reliably indicate a robust immune system or a well-nourished development – two factors that would positively contribute to health. For facial symmetry to be an evolved signal of health, however, the human face would need to be under direct (sexual)

selection pressure, arising from the mate choices of the opposite sex, to resist developmental perturbations and develop symmetrically. While more symmetrical faces are perceived as more attractive, it is not clear whether such preferences have translated into the necessary selection pressures. Because of the difficulties in ascertaining whether any given trait constitutes a signal or a cue, no clear consensus exists about this distinction for nearly any given health-related trait. For simplicity, we will refer below to all potentially health-related traits as cues, but do not mean to imply that such traits are definitely not evolved signals.

Theoretically, a health cue might reflect trait-based health or state-based health. By trait-based health we mean an intrinsic, genetic trait that predisposes an individual (and their offspring) to being healthy, like a robust immune system. By state-based health we refer to an individual's current state along any of a number of dimensions (such as being nutritionally replete or free of parasites) that can potentially vary over time.

Trait-based health cues and state-based health cues are not readily separable, with many traits potentially providing information about both trait and state health. For example, fat deposits on women would tend to be thought of as a state-based health cue, indicating adequate energy reserves. However, the capacity to effectively utilize nutritional resources and convert them to energy reserves likely varies genetically. So fat deposits on women could indicate both a genetic predisposition to efficiently metabolize food as well as providing reliable information about a woman's current energy reserves.

It is generally presumed that reliable phenotypic signs of health ought to increase perceived attractiveness. The circumstances under which human health cues (or signals) evolved, however, differ from those in which theories of trait-attractiveness-health links are typically tested. So while links between purported health cues and perceived attractiveness are readily reported (and we provide examples of many such cues below), links between purported health cues and objectively measured physiological health are less common. Modern medicine may have erased the

correlation between an ancestrally reliable health cue and actual health by buffering more susceptible individuals. For example, an individual with a weaker immune system would, in the absence of population-wide immunization, have endured a development with substantial disease and pathogen stressors, resulting in high levels of fluctuating asymmetry as an adult. In the presence of population wide immunization, however, that same individual may experience no more developmental stress, and subsequently exhibit no more fluctuating asymmetry, than an individual with a more robust immune system. By dramatically reducing variation in both health and health cues, modern medicine may make relationships between the two difficult to observe.

It is also true that conscious ratings of health (which some researchers have used, as discussed below) might not adequately reflect evolved responses to health-relevant cues. It is possible, for example, that a cue increases attractiveness (because it serves – or served – as a cue to health) without necessarily affecting conscious perceptions of health. Conscious ratings of health may more reliably reflect adaptive responses to state-based cues, rather than trait-based cues, since the former are generally the cues that we have the opportunity to consciously learn about as indicators of health. However, just because a physical trait increases conscious ratings of attractiveness, without increasing conscious ratings of health, should not necessarily rule it out as a potential health cue. Health cues could, in theory, affect attractiveness without us being aware that they are cues of health. Conversely, attractiveness will also be influenced by factors other than health, and so conscious ratings of attractiveness are by no means pure reflections of subjective responses to cues of health.

Cues to Health

A number of traits have been proposed as health cues, including facial traits such as symmetry, averageness, sexual dimorphism, adiposity, skin quality, and skin color, and body cues such as waist to hip ratio (WHR), waist to chest ratio

(WCR), body size, and body composition. As discussed above, while there is good evidence that these traits are perceived as healthy and attractive, evidence that they reliably indicate some aspect of physiological health is more mixed. Here, that evidence is reviewed.

Proposed Cues to Trait Health

A number of studies have shown that observers perceive symmetrical faces as more attractive, with authors speculating that low levels of fluctuating asymmetry reflects a strong immune system and ability to resist stressors such as pathogens and lack of nutrition during development (e.g., Rhodes et al. 2001). However, recent studies, including one using a large longitudinal database, have failed to find reliable connections to childhood health measures (Pound et al. 2014) in a modern industrialized society (UK).

Having a face that is close to the population average is also perceived as healthy and attractive, with authors suggesting that averageness indicates a lack of extreme, deleterious alleles, and some evidence suggesting that people with average faces may have been healthier during childhood and adolescence (Rhodes et al. 2001).

Sexual dimorphism – the femininity or masculinity of faces – has been found to have a role in attractiveness perception and is thought to reflect levels of sex hormones during development. The femininity of female faces is thought to be associated with estrogen levels, which are important in female fertility, and female facial femininity is perceived as attractive (Law Smith et al. 2006). Male facial masculinity, though hypothesized to be an honest signal of health, has shown mixed results, with most studies showing that women have a preference for slightly feminized faces, which may reflect more prosocial qualities (DeBruine et al. 2010).

Proposed Cues to State Health

Skin quality, including skin color (Stephen et al. 2011), has been shown to affect the perceived

health and attractiveness of faces, with redder, yellower, and more homogenous skin coloration being perceived as healthier and more attractive. These cues have been associated with aspects of health and fertility, with skin yellowness reflecting levels of carotenoids – antioxidant pigments obtained from fruit and vegetables in the diet, and which may be associated with improved immune and reproductive systems (Stephen et al. 2011, but see Foo et al. 2017).

Cues to body composition have also been found to play a role in the perception of health and attractiveness, with low WHR (thought to reflect estrogen levels) in women and low WCR (reflecting upper body strength) in men suggested as attractive cues to health. More recently, studies have suggested that body size (defined by body mass index, a ratio of weight over height squared) is more important than WHR (Tovée et al. 1999). However, BMI is a flawed measure of body size, since it conflates body fat and muscle. A recent study separated the influence of the fat and muscle components of body size, finding that men are perceived as healthiest and most attractive when their bodies contain healthy levels of fat and muscle, while women's bodies are perceived as healthiest with levels of body fat toward the low end of healthy, and most attractive with levels of body fat below the healthy range (Brierley et al. 2016). This has been interpreted to mean that while health is important in determining what appears healthy and attractive, some other influence, such as Western media or the association between youth (strongly positively correlated with fertility in women) and low body fat, may also be influencing perceptions of attractiveness.

The Relative Importance of Cues to State and Trait Health

Studies examining the relative contributions of these cues to perceptions of attractiveness have shown mixed results, with some finding that state cues (color) are more important than masculinity (Scott et al. 2010), while others suggest that trait cues, such as averageness, symmetry, or sexual dimorphism (Foo et al. 2017), are more important.

There may well be no one correct answer to the question of which cues are more important. With different cues reflecting different aspects of health, condition, and genetic quality, their relative importance should be expected to differ from population to population. As threats to health (including pathogen and parasite prevalence and nutritional stress) vary, so too should the relative importance to perceivers of cues to resistance to those different threats. Indeed, state and trait cues are difficult to fully disentangle because of the importance of trait (e.g., immunocompetence, ability to metabolize energy) to health state and of (current or past) health state to expression of trait health in the face and body.

Conclusion

Several cues have been shown to be robustly associated with healthy and attractive appearance of human faces and bodies. However, whether they can be considered valid cues to health depends on whether they accurately reflect aspects of underlying physiological health. Research into this second question is less abundant and results have often been inconsistent across studies. Modern medicine and dietary habits may make it difficult to observe relationships between health cues and actual health that were historically – and in some environments, perhaps currently – reliable. Research into the underlying (developmental and physiological) processes that give rise to purported health cues may reveal mechanistic links between such cues and actual health-relevant traits. Such findings would provide more robust and definitive evidence of the validity of health cues than has so far been reported.

Definition

Health markers are phenotypic traits that signal some aspect of mate quality, and these indicators may be used during mate choice. Health markers are generally considered honest, condition-dependent signals.

Introduction

Mate preference and mate choice in humans is notoriously complex. However, humans are the product of their evolutionary history and, in particular, two key processes: natural and sexual selection. To put this in perspective, we only need think back to our recent history over many hundreds of thousands of years. Under natural selection, traits that increased survival will have been favored. For example, individuals with a more robust immune system would likely live longer perhaps because they are more resistant to parasites and pathogens. And likewise, traits that indicate high quality, such as “good genes,” could be favored during mate choice. Under this scenario, sexual selection will favor particular individuals or genes because they will have higher reproductive fitness. The role of phenotypic traits in sexual selection has been the subject of considerable research in animals (reviewed in Andersson 1994) and, more recently, has gained traction in

evolutionary psychology (e.g., Thornhill and Gangestad 1996; Barrett et al. 2002; Rhodes 2006).

Phenotypic Indicators of Health in Animals and Humans

In animals, many species have dramatic sexual dimorphism such that males may have elaborate plumage in birds (like peacocks), bright coloration in lizards, or large antlers in antelope, to name but a few examples (Andersson 1994). These traits are clearly the target of selection, and they can be easily measured although what they may signal to a potential mate is far more difficult to discern. On the one hand, a sexually dimorphic trait may be arbitrary such as in the case of Fisherian runaway selection (Andersson 1994), or alternatively, it may be condition-dependent and signal quality (Hamilton and Zuk 1982). In the case of humans, while females are still the limiting sex (i.e., females are more choosy than males), male traits are perhaps not as obvious as in the animal kingdom. This raises two important questions. First, what male traits are important to females when they choose a mate, and second, what do these traits signal to a potential mate? Likewise, we should also ask what female traits are important to males because while females may be more choosy than males, male choice can play a significant role in fitness.

Physical Traits, Symmetry, and Mate Preference in Humans

Particular physical features are found to be attractive both within and across cultures (Langlois et al. 2000). While humans may use a wide range of traits linked to socioeconomic factors, personality, trustworthiness, etc., the focus here will be on phenotypic traits that signal health or quality. One commonly used measure of quality is fluctuating asymmetry (FA), which is a random deviation from perfect bilateral symmetry. Individuals with higher levels of FA are thought to reflect developmental instability – an inability to deal with environmental stressors during

development (Thornhill and Gangestad 1996). Measures of FA are influenced by exposure to pathogens or environmental contaminants, poor nutrition, parasite load, and numerous other factors (Rhodes 2006). Therefore, individuals with higher symmetry are considered more attractive and in better condition/health. In humans, body and facial symmetry are two sources of information available during mate choice.

Symmetrical human bodies are preferred and are likely condition-dependent because they are less likely to be associated with psychosis, premature birth, and inbreeding (Livshits and Kobylanski 1991). Similarly, among women with relatively large breasts, individuals with lower FA were more fecund (i.e., had more children; Møller et al. 1995). While this result suggests that breasts are sexually selected via male preference for larger breasts, more detailed study is required to determine the nature of breast FA relative to health.

The relationship between attractiveness and facial symmetry in humans has received considerable interest in the last two decades, particularly given the ease with which images can be quantified and manipulated on a computer (Rhodes 2006). Importantly, computer-generated images allow for the control of a wide range of confounding traits such as skin, hair, and eye color. So, do humans find symmetrical faces more attractive? It turns out that it depends on the method used to generate a choice of two computer images in which one of them shows less symmetry. In early studies a mirror image was created of one half of a face that was mirrored across a vertical midline (termed a chimera). This technique was later shown to be unreliable because it resulted in some distortion of features (see Rhodes 2006 for details). A more recent technique is facial blending, which produces a more reliable end-product. The two methods yield different results. Humans find symmetrical faces more attractive when the images are produced using facial blending but not when they are produced as chimera images. But do symmetrical faces signal FA, which theoretically is an important index of mate quality? Or, put differently, does facial symmetry signal health in humans? FA in humans is controversial, and

there are instances where studies have claimed to measure FA, but did not, or did not meet other essential criteria such as demonstrating repeatability. In a recent review, Rhodes (2006) concluded that there is little evidence that facial symmetry signals health, and recent meta-analyses have likewise come to this conclusion with respect to nonhuman animals. There is still work to be done before we can say unequivocally that facial symmetry reflects underlying health, but it is an intriguing hypothesis.

Condition-Dependent Signals and the Role of MHC and “Good Genes” in Mate Preference

Immunocompetence, or the strength of an individual’s immune system, has been touted as a target of selection because having offspring with a robust immune system is likely to raise inclusive fitness. This may be accomplished by selecting a mate with a complementary immune system in order to increase major histocompatibility complex (MHC) diversity (the genes governing immune responses; Winternitz and Abbate 2015). Put another way, humans should prefer MHC-dissimilar or MHC-diverse mates because a polymorphic MHC is a better tool kit with which to deal with rapidly evolving parasites and pathogens. It is of course more complicated than simply selecting a mate with a dissimilar MHC because there might be an optimal MHC diversity or there may be a specific MHC that correlates with “good genes” at that moment in time (reviewed in Winternitz and Abbate 2015). But how would an animal or a human know that a potential mate has an appropriate MHC complement? One possibility is that MHC is linked to a cue that is easily accessible to a receiver. In the case of humans, body odor has been linked to MHC such that favorable MHC genes correlate with more attractive body odor. Visual cues may also play a role. For example, men that were heterozygous in three loci for MHC genes were also rated as having more attractive faces than males that were homozygous at one or more of these loci (Roberts et al. 2005). While MHC condition-dependent mate preference in humans has been

controversial, the variation in results can in part be explained by differences in methods, and the weight of evidence is in favor of MHC preference playing a role in sexual selection (Winternitz and Abbate 2015).

Sexual Dimorphism in Facial Traits, Attractiveness, and Indicators of Health

During and after puberty, sexual dimorphism in facial and body features becomes more pronounced as testosterone levels rise in males and females suppress testosterone through estrogen production. Although testosterone plays a key role in reproduction, it is thought to suppress immune responses and therefore comes at a cost. At the same time, relative testosterone levels can be apparent in facial features. During and after puberty, males with higher levels of testosterone may develop higher cheek bones and more pronounced jaws (Winternitz and Abbate 2015). These traits may honestly signal health because males are able to pay the cost of expressing these traits although testosterone is immunosuppressive. Females are therefore predicted to prefer males with these traits. Indeed, populations or cultures from areas of greater parasite/pathogen prevalence place more weight on attractiveness (Gangestad and Buss 1993). This particular study used 37 different societies from six continents and five islands. Participants were asked to rate attractiveness using 18 traits, and this was assessed in relation to the prevalence of seven key pathogens prevalent in humans. Interestingly, this result held true for both sexes even when a range of confounding variables, such as average annual income, latitude, and geographical region, were controlled for.

Conclusion

While a great deal of research has focused on human evolutionary psychology in the past two decades, the field has a long way to go. In part, this has to do with some of the constraints of working on humans in a modern society with easy access to modern medicine and pharmaceuticals. For

example, taking birth control pills alters hormone profiles and may influence mate preference. Nevertheless, the ease with which we can sequence genomes and manipulate imagery for mate preference trials also means we have better tools with which to answer key questions.

How much evidence is there for condition-dependent, or health, signals in humans? As it turns out, the evidence is scattered and not substantial. First, the jury is out on whether facial symmetry, which is thought to be more attractive, is in fact an indicator of health. However, there is evidence that more attractive individuals have greater heterozygosity, which is linked to immunocompetence. Therefore, if females prefer males with more attractive faces and these males are heterozygous at MHC loci, there could very well be fitness benefits to such traits/health markers. Furthermore, attractiveness is also more important in societies where the risk of pathogen transmission is greater. Again, mate choice in these systems could be relying on health markers. Finally, aspects of body symmetry are linked to traits that influence fitness.

We particularly need more studies on societies far removed from Western influence where resources are more limited and, therefore, where health markers may be particularly informative with respect to fitness.

The sensory process by which auditory stimuli are perceived as sound waves by the ear(s) and then translated to neural signals and comprehended by the brain.

Introduction

The ability to hear (audition) is an impressive skill that differs greatly among species. For humans, the level of auditory discrimination that has developed over time has evolved not only due to outside influences of everyday noise, but also as a result of hearing's role in humans' complex speech and language production and comprehension. Hearing involves external and internal structures, as well as physiological processes that enable sound processing.

The Auditory Process

Essentially, the process of audition is catalyzed by changes in air pressure from the normal surrounding atmospheric level, which are the result of a stimulus such as noise from an object creating patterns of molecule vibrations in the air (Zemlin 1998). This change in air pressure results in sound waves, which project outwardly from the source. The sound waves are perceived first by the larger part of the ear called the pinna (outer ear), during which the sound waves are transmitted through the auditory canal. The sound waves reach the eardrum (tympanic membrane) through the Eustachian tube, which vibrates and passes the waves through the three small bones of the middle ear (malleus, incus, and stapes). The higher order processing of sound occurs in the inner ear, which contains the cochlea and hair cells in the organ of Corti that are responsible for transforming sound waves into neural signals and transmitting the signals into the brain via the auditory nerve. The auditory nerve, in conjunction with other cranial nerves, delivers the neural signals to several areas of the brain. First, the primary auditory cortex within the left posterior superior temporal gyrus receives sound input. Sound input is then passed

through secondary areas of the brain and the frontotemporal lobe, which is important for discriminating sounds as speech and nonspeech.

Hearing and processing speech sounds for humans have resulted in the development of mostly left-lateralized areas known as Broca's and Wernicke's areas, which are connected by a nerve fiber bundle called the arcuate fasciculus. These three entities form an important loop for speech production and comprehension in real-time through near-simultaneous comprehension and production, which is seamless in normally functioning auditory systems.

Evolutionary Anatomy of Hearing Structures

The most apparent observation that can be made about the evolution of the ears and auditory system in reptiles, mammals, and humans, aside from contributing to equilibrium and balance, is that they have developed over time to enable maximum awareness of auditory stimuli in the environment. This plays a role in readiness to respond to potential threats and make other important observations regarding safety, such as detecting the presence of others. In reptiles and earlier mammals, deeper auditory structures were present prior to outer structures developing (Webster and Fay 1992); as such, the pinna (outer ear) developed after the middle and inner ear, with the main purpose of enhancing the capture of sound to be processed by the deeper parts of the ear. In fact, recent research has established that the small bones of the ear in humans and other land mammals originated from gill structures that earlier vertebrates used to breathe under water (Brazeau and Ahlberg 2006).

Similar to other features in the human anatomy, the auditory system contains some vestigial structures that no longer dictate any auditory function. The auricular muscles of the outer ear, which in other mammals enable directional movement of the ears to better position the pinna to capture sound, are unnecessary for human audition due to the ability to manipulate positioning of the skull to further locate sources of sound (Hackley 2015).

Evolutionary Process of Discriminatory Properties

Humans can detect and discriminate between a great number of frequencies due to the highly developed auditory system. Due to the variety of speech sounds produced by humans, the complexity of verbal speech is matched by the development of heightened auditory ability in order to process all possible sounds in the social, as well as general surrounding, environment (Fritzsche et al. 2013). The ability to hear other humans' speech enables social interaction that is predicated on speech; goal-based group interaction, one-to-one conversation, and parent-child dyadic interactions are examples of important social relationships enabled by the auditory system's discriminatory capacity.

Conclusion

The evolution of human audition has not only enabled *Homo sapiens* to survive in response to hearing potential threats, but also enables speech sound discrimination essential to social interaction, which may facilitate group behavior and belongingness. The continuous improvement of technology has enabled in-depth study of the bone structure of the ear in the fossil record. Continued technological advances will likely enable even more discoveries regarding human hearing and its evolution.

Introduction

Love is heartbeat of life – *Lailah Gifty Akita*. The human heart is the symbol of love and emotions since ancient times. When we see our beloved, our heartbeats get faster and stronger in response to chemicals release from the brain (Freud Nour 2017). It is a vital organ which circulates the

blood in our body. It is located in the chest cavity in between our lungs and is the size of human fist. It pumps approximately 5 l of blood every minute. It carries oxygenated blood via arteries to the tissues and deoxygenated blood to the lungs via veins. Heart rate is one of the important vital signs and is measured by no. of contraction of the heart in 1 min and varies according to the physical need of the body (*Heart Matters* 2013). Changes in the heart rate can occur by some activities such as anxiety, depression, anger, physical exercise, drugs, disease or infection, and sleep. **According to American Heart Association**, normal resting adult human heart rate is 80–100 beats per minute (*American Heart Association* 2014). Normal fetal heart rate is 120–160 bpm in the in utero period. It can be measured by sonography from around 6 weeks, and the normal range of FHR varies during gestation (Nijhuis 2003). Electrical activity of the heart can be measured by electrocardiogram (Mason et al. 2007). Tachycardia refers to a fast resting heart rate, usually more than 100 beats per minute and when the heartbeats gets too slow, usually slower than 60 beats per minute, called bradycardia. When the heart rate is not beating in regular pattern, arrhythmia occurs (Jensen et al. 2013). An increased resting heart rate is an independent risk factor for mortality and a marker of poor general fitness and cardiorespiratory fitness (Jensen et al. 2013). It is directly associated with indicators of cardiovascular diseases such as hypertension, hyperlipidemia, etc.

Definitions

Heart Rate

According to NCI Dictionary of cancer terms, the number of times the heart beats within a certain time period usually a minute. It can also be defined as number of contractions of the heart ventricle (ventricles are lower chamber of the heart) per minute.

Contractions: **According to Merriam-Webster (1828)**, the shortening and thickening of a function muscle or muscle fiber.

Ventricle

According to WebMd, ventricles are lower pumping chambers of the heart. Heart has two ventricles – the right and left ventricle.

Is There Any Difference Between Heart Rate and Rhythm?

Heart rate is no. of beats per minute, while heart rhythm is regularity of rate or the pattern in which heart contracts. Normal heart rhythm is also known as sinus rhythm. Abnormal heart rhythm is called as arrhythmia which means heart is beating very fast or too slow or rhythm is irregular (Ine van loo 2019). The symptoms may be feeling of skipped a beat or added a beat or beating too fast or beating too slow. The heart has electrical or cardiac conduction system which is group of specialized cardiac muscle cells where electrical impulse is generated (in the SA node or natural pacemaker of the heart), and it sends signals to the heart muscle causing it to contract and to pump blood to the lungs and to the body. The electrical activity of the heart can be detected by electrocardiogram or ECG (Kléber and Rudy 2004). When there is problem with this system, person may feel arrhythmia. The symptoms may be like palpitation, dizziness, breathlessness, loss of consciousness, lightheadedness, etc.

Source of a Pulse: The Heart

Heart is a muscular pump, and a heartbeat is a contraction of the heart's muscle, forcing blood to move in the body through arteries. An electrical impulse causes the cardiac muscle to contract. An average healthy adult heart rate is 60 to 80 beats per minute. For older adults, normal is considered 60 to 100 beats per minute. Women generally have a higher rate than men (Heart Matters 2013).

The Result of Heartbeat: Pulse

A pulse is the expansion and contraction of an artery caused by the ejection of blood from

the left side of the heart. At certain points it can be easily felt (palpated) such as in the wrist (radial) or in the neck (carotid) of adults and older children. In infants and younger children, it can be palpated in the upper arm (brachial) (WebMd 2013).

So, pulse rate is same as heart rate. It varies from person to person.

Genes Affecting Heart Rate

Heart rates are affected through various physiological mechanisms. The predisposition of heart rates not only is wired by physiology but is deep rooted in the genetics. Studies have suggested a large number of genes associated with inheritable capacities generated by exercise. These genes (CDC141, PAX2, SOX5, and CAV, RNF220 and MCTP2, SCN10A and RGS6) are related to four basic attributes, neuronal development, cardiac development, cardiac rhythm, and neuronal life span (van de Vegte et al. 2019).

Arrhythmia

It is also known as cardiac arrhythmias; dysrhythmias or heart arrhythmias are a group of condition in which heart contracts too fast/too slow or with irregular pattern (Kobayashi 2018). Dysrhythmias are grouped from where they occur – in the upper chambers or receiving chambers of the heart (known as the right and left atrium of the heart), in lower chambers or contracting chambers of the heart (right and left ventricle of the heart), or in both chambers (Antzelevitch and Burashnikov 2011).

Bradycardia/Bradyarrhythmia

When the heart rate goes less than 60 bpm, it is known as bradycardia (Brazier n.d.). It occurs when the electrical signals are not formed into the SA node or are not sent to the lower chambers via proper channels. It can cause feeling of dizziness, weakness, lack of energy, or fainting

spells. The diagnosis can be made by doctors by evaluating the ECG, and the main treatment is implanting the pacemaker which is a device that generates the electrical impulses to regulate the heartbeat (*Heart rhythm society* 2015).

Tachycardia

When the resting heart rate is more than 100 bpm, it is known as tachycardia. Many forms of tachycardia depend upon where the heart rate begins. Series of rapid heartbeats that begin in the ventricles are known as ventricular tachycardia and if these fast heart beats starts above the ventricles, it is known as supraventricular tachycardia (Brazier n.d.).

Supraventricular Arrhythmia

Arrhythmia that starts in the atrium or upper chambers of the heart and heartbeat are above 100 bpm at rest. It is very common and less dangerous than ventricular arrhythmias (Tse 2016).

- **Atrial flutter:** it happens when the atria beat very fast causing the ventricle to contract insufficiently as well.
- **Atrial fibrillation:** it occurs when the atrium of heart contracts in irregular pattern and out of synchrony with lower chambers. It is the main cause of stroke, especially in elderly people.
- **Paroxysmal supraventricular tachycardia (PSVT):** this type of arrhythmia begins and ends suddenly. It can happen during vigorous physical activity, tends to occur in young people, and is usually not dangerous (Kobayashi 2018).
- **Premature/extra beat:** when the atrium contracts too soon, causing the heart to beat out of sequence, it leads to atrial premature contraction.

Ventricular arrhythmia: it starts in the ventricles, and these types of arrhythmia are very

dangerous and usually require emergency medical care (Sloman et al. 1971).

- **Ventricular tachycardia:** This type of arrhythmia is rapid, regular heartbeat usually more than 100 bpm lasting for few seconds or longer, and it prevents the ventricles from fully contracting resulting in less supply of blood (Ma et al. 2009). If immediate proper attention is not given, it may result in more lethal form of arrhythmia (Jordaens 2018).
- **Ventricular fibrillation:** Ventricular fibrillation is an abnormal heart rhythm in which disorganized electrical signals leads to the quivering of the ventricles instead of pumping normally and ventricle fails to pump the oxygenated blood to the brain & body resulting in to the sudden cardiac death or cardiac arrest. It is the most dangerous form of arrhythmia (Tse 2016).

Heart block is a type of arrhythmia in which the heart contracts too slow (bradycardia). Usually the electrical signals start in the SA node of the heart which is located in the right atrium and travels to atrioventricular node (AV node) and from AV node to wirelike structure To Bundle of HIS into the right and left ventricle of the heart, and they reach down to the bundle branches into the muscle wall of ventricles causing ventricles to contract (Kléber and Rudy 2004). If the electrical signals block in any step of this conduction, system leads to heart block (Brazier n.d.).

- **First-degree heart block:** it is the least serious type of heart block and usually does not require medical care. In this type of block, the electrical impulses are slowed as they pass through conduction system, but they all successfully reach to the ventricles causing the ventricles to contract (Levis 2011).
- **Second-degree heart block:** the electrical impulses are delayed further and further with each subsequent beat until a beat fails to reach ventricles entirely causing dropped or skipped beats. The person may feel dizziness, and they need pacemaker (Lim et al. 2018).

- **Third-degree heart block:** Complete heart block occur when electrical signals don't travel between upper and lower chambers of the heart. It is usually treated by implanting a permanent pacemaker (DiFrancesco 1993).

Treatment of Dysrhythmia

There are some tests for arrhythmia such as electrocardiograph (ECG), electrophysiological studies (EPS), Holter monitoring, echocardiogram, etc. that help to diagnose an abnormal rhythm of the heart (Jordaens 2018). Depending on the type of abnormal heart rhythm, the doctor recommends the medications (also called as anti-arrhythmic drugs) (Ganjehei et al. 2011), minor invasive procedures (like catheter ablation in which catheter is inserted into the heart via blood vessels to destroy the tissues in the heart which are allowing electrical signals to cause abnormal heart rhythm), implantable devices (such as pacemaker and implantable cardiac devices), and cardioversion (is a treatment modality in which controlled electrical shocks given to convert abnormal rhythm to normal rhythm) or defibrillation to prevent and or control it (Sloman et al. 1971).

Emotional State of the Mind and Role of Heart

The heart is not a merely organ which pumps the blood to the body, but it also sends the message to our brain about our emotional status. Earlier psychologist believed that emotions are purely a brain-generated mental expressions, but now many studies have found that there is a critical link between the heart, brain, and emotions. Many psychological factors such as grief, depression, anxiety, anger, hostility, loss of loved one/job, etc. contribute to poor heart health and cardiac diseases (Radcliffe Shawn). There is a two-way relationship between depression and heart disease (*National Heart, Lung, and Blood Institute* 2017). It has been linked to low-grade inflammation in blood vessels, which leads to

clogging or hardening of arteries and the rupture of cholesterol-filled plaque and also increases the production of stress hormones which increases the workload of heart by increasing the demand of blood flow. It activates platelets (a type of blood cell), making them more likely to clump and form clots in the bloodstream which finally leads to many cardiac problems like coronary heart diseases and heart attack. Depression also increases the risk of behaviors associated with poor physical health and unhealthy behaviors like smoking, drinking, physical inactivity, inappropriate coping skills to stress which can further lead to hypertension, arrhythmia, and heart failure (Smith n.d.). In the same way, people after cardiac surgery, heart attack or with any cardiac disease may have stress or poor response to stress, social isolation, low mood which are common and temporary for the first few weeks of recovery, but unmanaged stress can further increases the severity of depression and other mental problems (*Cleveland Clinic* n.d.). Everyone feels stress in different ways and reacts to it in a different way. Reducing stress or changing the response to stressing situation and maintaining the healthy lifestyle which includes physical activity, well-balanced healthy diet, and avoiding alcohol and smoking can actually lower the risk of cardiac diseases and better mental health (*American Heart Association* 2014).

Heart Rate and Heart Rate Variability

Heart Rate Variability

Heart rate variability (HR) is the time interval between two consecutive heartbeats. HRV is also known as interbeat intervals, R-R intervals, N-N intervals, etc. It is affected by a no. of factors such as age, pattern of lifestyle, diet, exercise, response to stress, etc. It is one of the indicator of health and disease stats of human body (ChuDuc et al. 2013). The intervals between beats are constant but vary between beats to betas; HRV can be used as a biomarker to indicate the influence of nutrition on mental and physiological health. An increased HRV is related to better general health, while decreased variability leads to a no. of

diseases which include diabetes, cardiovascular diseases, and psychiatric disorder. A study showed that a low HRV contributes to poor prognosis in patients who had survived after heart attack (Malik and Camm 1990). A well-balanced diet which includes Mediterranean diet, omega-3 fatty acids, B vitamins, probiotics, polyphenols, etc. can increase HRV, while high intake of saturated fat, flavored/processed food, alcohol, etc. is found to reduce HRV (Young and Benton 2018).

Evidences show that regular physical exercise has a significant impact on HRV. In healthy as well as patients with cardiac disease, regular aerobic exercise results in improvement of heart rate variability, and HRV can be used as diagnostic marker of overexercise and overtraining (Hottenrott et al. 2006), with increasing age function of heart decreases and leads to more cardiac events and morbidity and mortality related to cardiovascular diseases. Regular physical exercise in older people increases HRV, and a higher HRV is associated with high cardiovascular fitness and psychological health (Routledge et al. 2010).

Heart Rate Variability and Psychiatric Disorders

Cardiovascular diseases (CVDs) and mental illness are the most common cause of morbidity and mortality worldwide. CVDs are group of disorder which affects heart and blood vessels which includes coronary artery disease, chronic heart failure, arrhythmias, hypertension, etc. They account for 50% deaths in developed countries and 25% deaths in developing countries. The prevalence of neuropsychiatric illness and use of psychotropic drugs are equal (Shah et al. 2004). There is a strong relationship between CVDs and psychiatric disorders (Bacon 2019). Evidence suggest that people with mental disorders like schizophrenia, bipolar disorder, post-traumatic stress disorder, and anxiety disorder have an increased risk of developing coronary heart diseases (De Hert et al. 2018). Heart rate variability is changes in time intervals between consecutive heartbeats. Patients with depression without any cardiac diseases have low HRV which further

decreases with severity of depression and use of some antidepressants (Kemp et al. 2010). Depression has also an effect on fetuses of pregnant lady. A study showed that the fetuses of non-depressed women have high HRV as compared to women who had prenatal depression (Figueiredo et al. 2017).

Conclusion

The best and most beautiful things in the world cannot be seen or even touched – They must be felt with the heart – Helen Keller. Human heart is a pumping machine which provides oxygen and nutrients to the body and removes carbon dioxide and other wastes. It is also a seat of human emotions and feelings. Cardiac diseases are the leading cause of death for both men and women worldwide. For a healthy heart, one must have a healthy lifestyle (avoid smoking and heavy drinking, proper sleep, etc.), a well-balanced diet (such as use of healthy fats, whole grain, plenty of fruits and vegetables, plenty of water, etc.), regular exercise, and health checkups. Take care of your heart, and your heart will take care of you.

Height and Dominance

Definition

The relationship between height and dominance refers to a position in a hierarchy based on body height.

Introduction

In many mammalian species, dominance is positively associated with body size. All else being equal, larger individuals should be more likely to win than smaller individuals in contests. Building on findings from the animal kingdom, evolutionary psychologists have argued for similar associations between body size and dominance in humans. Indeed, it seems that both historically and cross-culturally body size is believed positively associated with dominance. One often noted example is that political leaders in Melanesia and Polynesia are referred to as “big men,” and they are often physically big men (Sahlins 1963). Similarly, today, in Western societies, positive associations between stature and political leadership exist. For example, ratings of American presidents’ leadership abilities positively correlate with their stature. Intuitively, one would therefore speculate that across the globe, dominance positively relates to height. In this encyclopedia entry, one aspect of body size, height, is discussed, and the evidence for a positive association between stature and interpersonal dominance is briefly reviewed.

Height and Dominance

Dominance interactions in humans remain understudied, and evidence for a positive relationship between height and dominance thus remains rather circumstantial. For example, research suggests that taller individuals might have more strength (Vaz et al. 2002), have better fighting ability (von Rueden et al. 2008), and are able to generate a larger force when striking (Carrier 2011) than shorter individuals. Taller individuals are also perceived as more powerful and stronger than shorter individuals (e.g., Huang et al. 2002). The reverse also holds that more powerful individuals are estimated as being taller (e.g., Fessler et al. 2012). Tallness also is found to be positively associated with perceived leadership qualities (Stulp et al. 2013). Taller individuals might have more authority in business settings (Judge and Cable 2004) or sports (Stulp et al. 2012). Finally, only a few studies have studied actual behavior which can be labeled as dominant in naturalistic

settings, such as having “right of way” (Stulp et al. 2015). For example, when faced with a narrow passage, taller individuals are more likely to take precedence than shorter individuals, all else being equal.

Conclusion

In conclusion, various strands of evidence corroborate the claim that tallness is positively associated with dominance. Yet, it is important to bear in mind that height is clearly correlated to a whole suite of other traits, including socioeconomic status, and as such teasing apart the independent effect of size itself for dominance could be difficult (especially given that we cannot experimentally manipulate human height directly). Moreover, it should be noted that any relationships found between height and interpersonal dominance tend to be weak. Perhaps, unsurprisingly muscularity appears to be a better correlate of interpersonal dominance, at least in perception studies (e.g., Sell et al. 2012). Finally, it must be noted that there is actually not that much research on height and dominance and that it is mostly limited to men. Therefore, while Western societies might have fewer dominance interactions due to the state monopoly of violence, height and dominance remain an interesting domain for further investigation, but studying the role of stature in dominant behavior in a naturalistic setting might prove challenging.

Helper at the Nest Among Nonhuman Primates

Eckhard W. Heymann

Behavioral Ecology and Sociobiology, Deutsches Primatenzentrum – Leibniz-Institut für Primatenforschung, Göttingen, Germany

Definition

A helper is an individual that contributes to breeding by conspecifics through providing alloparental

care. The helper may be nonreproductive, or its own reproduction may have failed.

Introduction

In the majority of primate species, infant care is provided solely by mothers, although other group members may interact with infants and carry them for short periods. In some pair-living primates, social/genetic fathers may provide paternal care. Particularly in night monkeys and titi monkeys, males are the principal infant carriers, while the contribution by helpers is negligible (Huck and Fernandez-Duque 2012). Regular helping behavior through transport of and food sharing with infants occurs in marmosets and tamarins, of the New World primate family Callitrichidae. Callitrichids (except Goeldi's monkey) are characterized by flexible mating systems, including polyandry (particularly in tamarins), monopolization of reproduction by a single female per group, and twin births (Goldizen 1988). The energetic costs of carrying twins which at birth may correspond to 15–20 % of maternal body mass have been postulated as a driver for the evolution of the helper system in callitrichids (Goldizen 1990).

How Do Helpers Help?

In callitrichids, helpers basically provide two types of infant care: transport and food sharing. Transport is by carrying infants on the back. During the first weeks of life, twins are usually carried together, but when they become heavier are transported separately. Infant carrying ceases after 3–4 months of age; thereafter helpers carry infants only in case of danger (e.g., predatory threats).

Food sharing extends for almost the entire first year of life, although it diminishes in frequency when offspring become older. Shared food mainly includes prey (arthropods, small vertebrates) that infants are not yet capable to capture and fruits that require force for opening the husk. Food sharing may be passive through not resisting “stealing” by infants, but in some callitrichids, food may actively be offered, including the emission of “food calls.”

Is Helping Costly?

As infant body mass is high in callitrichids, it can be reasonably assumed that their transport incurs energetic costs. In fact, captive studies have demonstrated that helpers lose body mass during periods of infant carrying (Sánchez et al. 1999). Changes in activity budgets, particularly the reduction of feeding and foraging, in wild callitrichids suggest similar energetic costs (Huck et al. 2004). It is conceivable that infant carrying might also reduce the speed of escape, thus increasing the risk of predation for helpers.

Why Do Helpers Help?

The costs incurred by helping must be compensated by benefits to maintain this behavior evolutionary stable. By helping with the rearing of younger siblings, helpers may gain inclusive fitness benefits. High levels of intragroup genetic relatedness suggest that such benefits might indeed be realized (Huck et al. 2005). However, intensive helping has also been observed in individuals unrelated to infants, suggesting that other benefits must be realized as well. Such a benefit could be an increased probability of survival by remaining in a group until opportunities for own reproduction emerge; helping could then be a form of “pay to stay.” Inheritance of breeding positions by female helpers suggests that such a benefit can also apply (Goldizen et al. 1996).

Helpers may receive more allogrooming from reproductive females (“pay for help”; Lazaro-Perea et al. 2004) which renders social, psychophysiological, and/or hygienic benefits as an additional possibility. Whether or not helpers can benefit from gaining rearing experience for own later reproduction is contended.

Does Helping Make a Difference?

Several studies, both in captivity and in the wild, have shown a relationship between the number of helpers present in a group and the probability of infant survival (Culot et al. 2011; Rothe et al. 1993). Group productivity can thus be increased by

helping, although the ideal measure for such an effect would be the amount of help received per infant rather than the number of helpers.

Helpers in Other Primates

Primate infants are generally attractive to other group members, including older siblings, but also related and unrelated adults who may handle, play, or carry infants. This is particularly noteworthy in capuchins and squirrel monkeys (Huck and Fernandez-Duque 2012), the closest phylogenetic relatives of the callitrichids. However, the amount of maternal care always exceeds the care provided by others, unlike callitrichids, and so far there is no evidence for an influence of the number of caretakers on infant survival.

A special case is grandmothering: post-reproductive females caring for the offspring of her daughters. Grandmothering has been observed in some nonhuman primate species.

Conclusion

Among nonhuman primates, helpers at the nest in the strict sense are uniquely found among the New World marmoset and tamarin monkeys. Helpers provide transport and food for heavy infants to whom they may or may not be related. Benefits of helping may mainly rest in inclusive fitness gains and increased survival by remaining in a group. Helping may increase the probability of infant survival.

Helpers at the Nest

James Malcolm

University of Redlands, Redlands, CA, USA

Definition

A breeding system in which offspring from the previous breeding period remain with the parents and play a role in raising young.

Introduction

The term helpers at the nest is typically applied to species in which young animals of both sexes delay dispersal and remain in their home territory through at least one breeding cycle. The proportion of young remaining and the period of time that they spend as helpers are both variable. As the name suggests, the phenomenon has been recorded most often in birds with examples known in over 200 species (mostly monogamous, passerine species). Among mammals, the system is seen in most members of the dog family (Canidae) and many marmosets and tamarins (Callithridae) and sporadically elsewhere, e.g., beavers (*Castor canadensis*). There are a few examples from fish (Hatchwell and Komdeur 2000). The term is sometimes applied to communal breeding systems with delayed dispersal predominantly by one sex. In this context, it has been applied to social insects and to humans.

Main Text

The evolutionary costs and benefits to helping need to be analyzed in terms of inclusive fitness where costs and benefits apply both to the individual involved (direct fitness) but also that individual's effects on the reproductive success of genetic relatives (indirect fitness). Indirect fitness is usually a product of altruistic behavior (usually feeding the offspring of other individuals). Some of the first and most detailed studies of altruism directed at kin (kin selection) come from species with helpers at the nest.

Helpers do all the caring behaviors of their parents notably protection (babysitting and chasing predators), carrying young (especially in marmosets and tamarins), and playing with young. However, the commonest and probably most useful action is providing food (often by regurgitation).

Do helpers help? The majority of studies with good quantification show increased fitness of young when helpers are present. However, help can depend on current resources. In African wild dogs (*Lycaon pictus*), there is an overall positive

correlation between pup survival and number of helpers. However, in a time of food shortage the helpers stole food regurgitated to the pups (Malcolm and Marten 1982). In several species, the parents contribute less in the presence of helpers and may benefit from enhanced survival (Heinsohn 2004).

Under what circumstances does helping behavior evolve? Helping depends on the balance between the direct and indirect components of fitness. However, it seems that in most cases the direct components are more important. Direct fitness depends on the chance of successful emigration versus the benefits of stay in the natal territory. Helping is usually seen in saturated habits where there is very limited opportunity for successful dispersal. The benefits of not dispersing can be enhanced through the opportunities for care for siblings, but animals seldom appear to forgo a chance to disperse and have the opportunity to raise their own offspring.

Conclusion

The retention of offspring into the breeding group is a feature of most forms of cooperative breeding. Helpers at the nest is a term for this philopatry mainly studied in birds. Breeding systems with helpers at the nest have yielded some of the most detailed information on inclusive fitness theory.

Definition

Helping can be defined as a voluntary act which directly or indirectly benefits an individual; the helper may be rewarded or unrewarded or pay a price for helping. In evolutionary psychology, for these forms of prosocial behavior the concept of altruism is used. Altruism differs from helping in that there is no expectation of a return. In other words, altruism is behavior which increases the fitness of the recipient at a cost to the actor (reducing the fitness of the actor), who does not expect to be rewarded (Barcaly 2011). Altruism is

an evolutionary puzzle: a trait that appears to reduce the fitness of the individual who possess it. One would expect that natural selection operates against helping others at a cost to oneself, because such behavior probably reduces the resources the altruistic actor has available for survival or for reproduction. The mechanism by which altruism could have evolved is puzzling.

Introduction

Hamilton was the first to demonstrate that a fitness-reducing trait could spread in populations if it had sufficient *extended phenotypic effects*; in other words if a trait produces beneficial outcomes for other members of the same species, who presumably possess the same trait due to genetic relatedness, it can be adaptive. Thus, Hamilton connected kinship to altruism, suggesting a new perspective on evolutionary success: *inclusive fitness*. The evolutionary success of a gene depends on the number of copies of itself it leaves in the next generation, i.e., the maximum number of viable, direct offspring of the individual possessing the gene. Hamilton argued that, to some extent, other members of the population share identical genes so a gene may also increase the number of its copies by indirect reproduction. More specifically, according to Hamilton our genetic relatives (e.g., not only parents, siblings but aunts, uncles, etc.) have the same version of genes or alleles we have in proportion to the ratio of our common ancestors. The support of the reproduction and survival of individuals who may possess the same genes (traits) as oneself (i.e., family members or genetic relatives) increases one's evolutionary success. Without doubt close relatives or kin have the highest number of identical genes. Inclusive fitness can be defined as the result of the number of offspring produced directly by an individual plus his or her contribution to the reproductive success of genetic relatives (Hamilton 1964). For example, the alarm call of belding ground squirrels can be explained by this model. An individual squirrel gives an alarm call to warn others in the local group of the presence of a predator; this act puts the

alarm-sounding squirrel at a disadvantage because the call signals its location to predators, increasing the likelihood that it will be killed; however, by sounding the alarm the squirrel protects its relatives and others in the local group. Belding's ground squirrels live as groups of close genetic relatives, and in this context sounding the alarm can enhance the reproductive success of kin (who share the trait/gene for giving alarm calls) by protecting them from the predator, thus resulting in more offspring with the alarm-sounding trait in the next generation. Of course, altruistic behaviors are only favored by natural selection if they lead to more copies of the gene (trait) concerned being passed on than would be achieved by direct reproduction (Mateo 1996).

Hamilton's Rule

As well as developing the concept of inclusive fitness Hamilton suggested a formula to define the conditions under which altruism could spread in a population: $C < r \times B$. This inequality is also known as Hamilton's rule. C represents the cost of the altruistic individual, like time, effort, and resources utilized for helping, which limits the survivorship or reproduction of the helper. The recipient's possible benefits derived from the altruistic act are represented with B and r is the *degree of relatedness* between actor (altruist) and recipient (individual in need). As explained above, kin probably share common genes, because they have one or more common ancestors or are ancestors or descendants of each other. Accordingly, the degree of relatedness is an arithmetic formula for the probability of sharing genes with relatives. In effect, Hamilton's rule describes the two major factors defining the evolutionary consequences of *kin altruism*. Accordingly, altruism can be an evolutionarily stable strategy, if (1) the probability that the helper shares genes with the individual in need (r) is significant and (2) if the fitness benefit to the helped kin exceeds the fitness cost to the altruist ($B > C$) (Dawkins 1982).

Kinship is privileged in all cultures, and in certain cases (emergency situations) individuals

will give precedence to even the weakest kinship bond over the most beneficial nonkin relationship. Nevertheless, altruism toward kin and reciprocity with nonkin may have common genetic roots because of their functional correspondence. Individuals have to recognize each other and remember the history of their relationship; consequently, humans have to be able to memorize individuals and discriminate them from others according to certain cues or features. Moreover, they have to remember previous outcomes of the relationship, that is, individuals have to be able to calculate the costs and benefits of that particular relationship. The evaluation of a relationship is affected by the frequency of social exchange with a particular individual. Frequent social exchange may lead to creation of a sense of familiarity, and familiarity implies genetic relatedness because in evolutionary environments close and distant relatives lived near to each other. This means that kin altruism is inherently error prone because of the difficulties of evaluating degree of relatedness as well as judging the costs and benefits of altruism, especially in emergency situations, when decisions have to be made rapidly (Burnstein 2005). This problem raises some important questions: How can we assess the benefits and costs of an altruistic act and how we evaluate degree of relatedness?

Hamilton (1964) also suggested the existence of evolved mechanisms enabling individuals to discriminate kin from nonkin. Subsequent work was dedicated to whether and how animals and humans recognize kin, even collateral kin (e.g., siblings, nieces, nephews, aunts, and uncles). These studies showed that humans are able to recognize kin but the interpretation of evidence is ambiguous, because it depends on how we define kin recognition. The broadest definition of kin recognition describes it as the facility for distinguishing kin from nonkin or recognizing kin. In the case of altruism, it is important to have reliable cues for identifying relatives and avoiding deceivers (think of the birds that care for a cuckoo's chick because they use spatial signals to identify their own offspring, assuming "all chicks in my nest are my own"). Evaluations of genetic relatedness should be based on genetic

similarity or on signals associated with kinship (Penn and Frommen 2010).

Estimating Genetic Similarity

Hamilton (1964) proposed that it was possible to evolve for a gene that is capable of recognizing copies of itself in other individuals and that such a gene would trigger behaviors designed to benefit individuals who shared it. This signaling function is also known as the *green beard effect* (Dawkins 1976). Thus, a greenbeard gene (1) produces a rare phenotypic trait (e.g., a green beard), (2) enables the recognition of that trait/phenotype in others, and (3) promotes altruistic behavior towards individuals carrying that trait. The evolution of such greenbeard genes is highly improbable, and it has in fact been observed in only a few species. This rarity is presumably because such genes are vulnerable to cheating: individuals may fake the phenotype in order to gain benefits without acting altruistically (Penn and Frommen 2010). Several mathematical simulations (e.g., Jansen and van Baalen 2006) have shown that genes enabling altruism must continuously change their phenotypical cues to avoid exploitation by defectors or social parasites. Thus, it is plausible to suggest that this continual alteration may lead to more stable evolutionary dynamics of greenbeard genes.

In addition to theoretical assumptions discussed above there are several studies with humans suggesting a genetic locus for kin recognition cues, namely the major histocompatibility complex (MHC), a group of genes that control immunological self/non-self-recognition and are thought to be associated with kin recognition mechanisms (Brown and Eklund 1994). Body odor is influenced by MHC genes, which differ between families, and may therefore act as a kin recognition label. In a double-blind study women were asked to rate T-shirts worn for a few days by men to indicate how attractive they found the men on the basis of their body odor. Women found men with different MHCs more attractive than men with more MHC similarity but only if they were ovulating. The reverse effect was found in women

taking oral contraceptive, that is, the odor of MHC-similar men was rated more attractive than the odor of MHC-dissimilar males (Wedekind et al. 1995). Apparently, women are able to recognize nonkin men and find them desirable in cases where being genetically nonrelated reduces the chances of inbreeding. The reverse effect suggests that detecting MHC similarities facilitate the formation of cooperative bonds.

These findings suggest that evaluations of genetic relatedness are based, to varying degrees, on judgments of phenotypic similarity which involve comparison of a stimulus (e.g., the phenotype/trait of an individual) and a standard. Kin recognition mechanisms can be distinguished according to the source of the standard: *familiarity* or its ecological correlate, *proximity* requires that individuals memorize traits/phenotypes of kin and compare this memory trace with their perception of another person's trait/phenotype in order to judge relatedness. Another mechanism, *phenotype matching* uses self-referential cues for the comparison between stimulus and standard. The individual develops a "kin template" based on phenotypic cues learned through self-observation or from relatives it was reared with. The phenotypic cues presented by others are compared with this kin template to make kin recognition judgments (Penn and Frommen 2010). Both these mechanisms require similar operations and templates derived from experience with others, self-observations or genetic programming. This means that in certain circumstances it is not possible to distinguish between the effects of greenbeard genes and familiarity or phenotype matching. For example, there is a greater genetic similarity in blood antigens between spouses than between randomly chosen couples, and likewise long-term friends have more similar blood antigens than unacquainted pairs (Holland 2012). However, individuals of similar ethnicity and nationality tend to live near one another, even in modern societies (Glazer 1975), and these cues (i.e., ethnicity and nationality) predict blood group and are associated with proximity, which is a reliable predictor of relationship choices, so spouses and friends could share the same blood type whether or not they are able to detect genetic relatedness.

Familiarity-Dependent Kin Recognition

In species where young individuals stay with parents and other family members during the first period of their life – as humans do – offspring learn kin phenotypes and use the information later on to recognize kin (e.g., Westermarck 1921). The *Westermarck effect* was the demonstration of this kind of discrimination in humans: children who live in close proximity during the first few years of life become negatively imprinted and consequently in adulthood they reject each other as sexual partners.

There is a large body of evidence suggesting that social learning influences human kin recognition, principally in where matching abstract, alterable phenotypes such as personality traits is concerned. Some studies have shown that infants are able to identify kin even after limited experience: they can distinguish the voices of their mother and an unrelated woman a day after birth. Several weeks after birth infants are able to discriminate between their mother and unrelated women on the basis of their faces while mothers can identify their child from a set of photographs five hours after birth (see Bjorklund and Pellegrini 2002 for a review).

Phenotype Matching

The other group of kin recognition mechanisms is based on evaluation of self-resemblance, i.e., individuals compare the cues presented by others with their own cues for a given trait. The most salient social cues for humans are facial characteristics, and it is therefore assumed that facial resemblance plays an importance role in the detection of genetic relatedness.

Studies investigating the effects of facial resemblance use facial morphing techniques, such as merging images of two different faces to give a “compound face” (i.e., a morph) that shares features of both original faces. Facial morphs which are intermediate between the two original faces enable researchers to compare the impact of self-morphs (i.e., composite faces combining the subject’s face and a stranger’s face) and non-self-

morphs (i.e., compound faces combining the facial features of two strangers) on social judgments. A considerable body of experimental evidence confirms that individuals are able to detect self-resemblance in faces and that they treat such faces differently; subjects trust self-morphs more than non-self-morphs, even when the non-self-morph is familiar. Facial morphs of celebrities provide familiarity but no self-resemblance. Subjects favor self-resembling morphs over non-self-resembling faces and even over familiar non-self-morphs (DeBruine 2002). Moreover, Bressan and Zucchi (2009) found that both dizygotic (DZ) and monozygotic (MZ) twins preferred self-morphs over morphs based on the face of their twin.

Assessing Costs and Benefits of Altruism

Several factors were identified to have influence on fitness costs and benefits of helping. For example, helping only occurs, if the actor has available resources or control over required resources or skills. Another significant factor is the value of the recipient, which is defined by several characteristics of the individual (e.g., age, sex, status, etc.). Accordingly, for example, age of the recipient can change the cost-benefit ratio: Older individuals have less capacity and opportunities to use help efficiently and convert to reproductive success than younger individuals. Consequently, evaluating cost and benefits depends on contextual parameters and on the characteristics of the recipient (Kurland and Gaulin 2005).

Field studies have provided some evidence for the existence of kin altruism, showing, for example, that genetic relatedness influences resource distribution: For example, when fishermen divide their catch they give a bigger share to close relatives than to others (see Burnstein 2005 for more examples). Nevertheless, beside field observations, experimental analyses could provide some insight into the proximate mechanisms to evaluate the ability of individuals to benefit the group and their willingness to help/cooperate.

The prisoner’s dilemma (PD) is an experimental game used as a model for cooperative behavior (and other real-life interpersonal situations). In a

basic PD, two interacting individuals (A and B) have to decide whether to cooperate or betray and the amount of money they win will depend on the decisions both parties make. If A and B both betray each other both lose a moderate amount of money; if one of them betrays and the other offers cooperation the betrayer will win a certain amount of money while the cooperator loses more than in the previous scenario (betray-betray); if both opt to cooperate they will both win a modest amount. Most studies use an iterative PD in which the same individuals play each other repeatedly as thus have opportunities to punish the other player for his or her previous decisions. It has been shown that the most effective strategy is “tit-for-tat” (TFT), i.e., making the decision one’s partner made in the previous round. The evidence suggests that in most cases individuals display a systematic bias towards cooperative behavior, which is not compatible with the predictions of a simple model of self-interested action (Nowak and Highfield 2011; Stewart and Plotkin 2012). Hamilton’s inclusive fitness theory predicts that PD pairs should be more trusting and cooperative if they are genetically related. Studies on facial resemblance provide some indirect support for this (e.g., studies of DeBruine 2002): Subjects were more trusting and altruistic towards self-morphs than non-self-morphs. A study by Segal and Hershberger (1999) provided more direct evidence of cooperation between kin. They compared the performance of MZ and DZ twins in PD game and found that MZ pairs exhibited noticeably more cooperation than DZ pairs. In general, familiarity encourages individuals to display trust and altruism in individuals: For example, subjects judgments about whether a person is typically altruistic or not were improved if they had watched a video clip of that person telling the Little Red Riding Hood story, which created familiarity (experiment 1 in Brown et al. 2003).

Other studies have shown that genetic relatedness has a systematic impact on assessments of the costs and benefits of altruism. Generally, higher genetic relatedness is associated with a higher probability of helping, in accordance with Hamilton’s rule: The larger the benefit-to-cost ratio, the more likely altruists will discriminate

and favor close kin (see Burnstein et al. 1994). Moreover, individuals prefer to distribute their help so as to maximize the reproductive return, based on genetic relatedness (i.e., they will choose to help two siblings rather than one but will prefer to help one sibling rather than two cousins etc.). For example, Wang (2002) asked subjects to imagine situations in which their decisions affect a six-member kin group, containing two close relatives of the same sex, two distant relatives of the opposite sex, and two unspecified relatives. Subjects have to choose one of two options: a medical procedure which certainly saves two male or two female kin (either close or distant kin) and a procedure with a 33 % probability to save the whole six-kin group. Additionally, half the subjects were asked to imagine that the group was made up of their own relatives and half that it was made up of another person’s relatives. When subjects were making decisions about their own relatives 40 % of them chose the certain procedure to save close relatives but only 20 % did so to save a pair of distant relatives.

Conclusion

Hamilton’s theory of inclusive fitness offers an explanatory account of the evolutionary stability of the altruism; according to Hamilton’s model altruism occurs when the costs do not exceed the reproductive benefits, which are weighted according to the genetic relatedness of altruist and recipient ($C < r \times B$). Hamilton’s rule is supported by ethnographic and experimental research showing that in line with the predictions of inclusive fitness theory individuals unequivocally favor kin over nonkin and prefer close kin over distant kin. Furthermore, these preferences are stronger in emergency situations, i.e., when (reproductive) cost-benefit ratio is more salient. Under this model, kin altruism depends critically on how accurately individuals are able to estimate genetic relatedness and evaluate the costs and benefits for helping. Despite a large number of studies, the computational mechanisms underlying these processes remain unclear. There is some evidence suggesting that individuals use a

genetically programmed template to recognize familiarity; however, co-rearing or early childhood experiences could also generate an inner representation of a “family schema” via social learning mechanisms. Familiarity-based kin recognition could also occur via phenotype matching, that is, on the basis of assessing resemblance to self. Whatever the cues used for kin recognition, it seems plausible that individuals have some mechanism for taking into account degree of genetic relatedness when evaluating the costs and benefits of altruism. In conclusion, altruism towards kin is based on complex calculations and assessments which are affected by familiarity, situational cues, and the reproductive “value” of the recipient (based on age, health, etc.).

Definition

Inclusive fitness is the sum of direct (personal) fitness and indirect fitness of the organism. Direct fitness is the number of offspring the individual procreates, whereas indirect fitness is defined by the number of offspring begotten by the genetic relatives of the individual. To the extent of the genetic relatedness, descendants of relatives share a proportion of copies of the individual's genes. Thus, helping genetically related individuals, also aids the reproduction of the shared genes, providing additional (indirect) benefits for the altruist (Hamilton 1964).

Introduction

Both direct and indirect fitness benefits could account for the evolution of altruism, and therefore in several cases it is difficult to separate them. Hamilton suggested a formula to define the conditions under which altruism could spread in a population: $C < r \times B$, also known as *Hamilton's rule*. In this inequality C is the fitness cost of the behavior to the altruistic individual, B is the benefit of altruism for the recipient, and r is the *degree of relatedness*. Since kin share one or more ancestors or are ancestors or descendants of each other they are likely to possess some common genes (or traits). The degree of relatedness gives the probability of sharing genes with relatives. In

effect, this formula states that the evolutionary consequences of being altruistic towards kin depends on the probability that the altruistic individual shares genes with the recipient (kin) (r) and the extent to which the benefit to the kin exceeds the cost to the altruist ($B > C$) (Dawkins 1982).

Indirect Benefits for the Helper

Field studies have provided some evidence for the existence of kin altruism, showing, for example, that genetic relatedness influences resource distribution: when fishermen divide their catch they give a bigger share to close relatives than to distant kin or non-relatives (see Burnstein 2005 for more examples).

However, costs and benefits of altruism depend on several situational factors, such as the availability of resources or the actors' ability to control or utilize these resources. Another key factor is the value of help to the recipient, which depends on several characteristics (e.g., age, sex, status, etc.). For example, as a consequence of aging older individuals are less efficient than younger individuals in using resources to reproduce or nurse offspring. Beside situational factors, genetic relatedness has also a systematic impact on assessments of the costs and benefits of altruism. Based on Hamilton's rule, higher genetic relatedness is predicted to be associated with a higher probability of helping. Accordingly, some studies showed that the larger the benefit-to-cost ratio, the more likely altruists will discriminate and favor close kin over distant kin and over nonrelatives. Moreover, individuals prefer to distribute their help so as to maximize the reproductive return based on genetic relatedness (i.e., they will choose to help two siblings rather than one but will prefer to help one sibling rather than two cousins, etc.; see Burnstein 2005).

Direct Benefits for the Helper

There are two different forms of direct fitness benefits for helpers: (1) direct benefit as a by-product or "automatic" consequence of

helping and (2) social benefits (advantages within the group).

By-Product Benefits

Altruistic behavior toward group members can lead to a larger group size, which can be beneficial to all members of the group, because it lowers the mortality within the group. An enlargement of group size can increase the likelihood of survival through enhancing catering or outcompeting other groups by means of mutual helping between group members (Clutton-Brock 2002). For example, there is a good evidence that subordinate individuals help raise unrelated offspring in order to increase group size but at some later point, if these subordinates obtain dominance, they can take account of being supported by those offspring (*delayed reciprocity*). The help in rearing offspring that are not the individual's own is termed as *group augmentation* and has been suggested to be important mechanism in several social species (see Griffin and West 2002).

If group members are related, the by-product benefits of altruism can provide indirect benefits as well, because if the altruist helps a relative or kin they may share the benefits of the altruistic act. A good example for this effect is the “*helping at the nest*”: adolescent (and often sexually mature) offspring remains in the habitat of the family to help the parents raising subsequent offspring, instead of investing of the own reproduction (West et al. 2007). In several societies, mothers expect their juvenile girls to help with rearing their siblings and encourage them to do housework (e.g., Bereczkei and Dunbar 1997). On the one hand, this assistance could increase the reproductive success of the mother and so it provides an indirect benefit for the older sibling. More direct advantages for the helper might are (Dickinson and Hatchwell 2004):

Protection: staying in the parental habitat could be more safe for the young one, who is yet not in his/hers prime.

Skill training: helping at the nest is attached with practices which are requisites of subsequent

reproduction or survivorship (e.g., nursing babies, cooking, etc.).

Social Benefits

For most of the species, individuals show an enhanced survival in a group rather than alone or few in numbers. Therefore, altruism can provide one of the best strategies for avoiding ostracism or being punished to violate norms. Some empirical evidence support this notion, showing that individuals who help or pretend to helping other in the group can successful avoid punishment (see Griffin and West 2002 or West et al. 2007 for examples).

Under certain conditions, for example, to help someone, who is unlikely able to return the favor advertises the helper's generosity, available resources, and other socially desirable traits. Because helping is associated with significant fitness costs, altruism can be considered as an honest signal of several personal qualities. Advertising such qualities enhances the mate value of the individual, which increases the probability of reproduction, and so it may contribute to the fitness of the helper. Therefore, the most common result of altruism within the group is the increase of social status of the helper (Zahavi and Zahavi 1997). Although evidence for this assumption is limited, in some studies, participants preferred individuals, who tended to be altruistic to others in earlier interactions. In some cases, the reputation rises even if the individual only aims to act altruistically (Bereczkei et al. 2007). Furthermore, individuals with an advanced social status appear to be more beneficial partners in social exchange situations. Thus, such individuals are preferred as partners in establishing cooperative alliances.

Conclusion

There is a considerable overlap in the mechanisms of direct and indirect fitness benefits of helping. More specifically, helping can provide a fitness benefit for more than one reason and because the different proximate mechanisms, direct and indirect benefits can play different

roles in the evolution and maintenance of helping behavior. Moreover, kin altruism does not necessarily imply that indirect fitness is the main factor driving altruism, even if it was presumably required for the initial evolution of helping. One of the major tasks of contemporary studies is to estimate the relative impact of direct and indirect fitness benefits on observed forms of helping.

Helping and Reproductive Value of the Recipient

Definition

Considerable evidence support the basic assumption of Hamilton's inclusive fitness theory showing that individuals behave altruistically towards kin (see Burnstein 2005. for a review). However, there are several factors, which affect the probability of behaving altruistically toward kin, like reproductive value of the recipient. The "evolutionary logic" behind this bias corresponds with the variability of an individual's potential to reproduce offspring. The *reproductive value* of an individual is determined through its current and future reproduction, i.e., its expected summarized contribution to the next generation of the population. Future reproduction (or *residual reproductive value*) represents the investment of the individual of its own growth and survivorship. It is suggested that higher investment in current reproduction reduces future reproduction, because it expropriates resources from growth and survivorship. However, resources invested in growth will benefit the individual in the future through the increase of number of offspring and reproductive episodes (Fisher 1930).

Introduction

Several disorders affect the reproductive success of the individual through limiting mating frequency or fertility which induce a decrease of

the likelihood of passing on genes. Accordingly, individuals are less likely to act altruistic toward kin with such *reproductive limitations* because the lower probability of passing on the gene responsible for altruism. There is some evidence to support this notion, for example, it was observed that mothers provided less maternal care (e.g., length of breast feeding) to weakly infants (i.e., low birth weight) compared to healthy infants (Berezkei 2001).

However, reproductive limitations differ in their conspicuousness and in the extent to which they affect the reproductive value of the individual. For example, a homosexual young adult male dispose no visible reproductive limitation, although his homosexuality could (but not necessarily do) impede the production of offspring. The aim of this entry is to provide a short review of factors affecting the reproductive value of an individual.

Sex of the Recipient

In several studies, female relatives are favored over male relatives by altruists of both sexes suggesting the significant influence of the sex of the recipient in evaluation of the cost-benefits ratio of an altruistic act (e.g., Burnstein et al. 1994). Although women have limited reproductive capacity, because the internal fertilization, they can be absolutely certain about being genetically related to their child. Contrarily, men always face the (hypothetical) possibility that the child has been fathered by another man. This phenomenon is called *paternal uncertainty*. Accordingly, it is more beneficial to help a female relative compared to a male relative, since the helper can be more certain that the recipient transmits their shared genes.

Age of the Recipient

Aging affects the reproductive success of the individual and accordingly it also influences the extent to which the recipient can utilize the benefits of the help. As a general rule, older individuals are supposed to be less efficient at converting

resources into offspring. In good agreement with this hypothesis, Burnstein et al. (1994) found that the preference of female kin over male kin in helping fades away with the increase of the age of the target person. At the age level close to the onset of menopause, or over this period, the likelihood of reproducing offspring drops significantly, thus it is no more favorable to support female over male kin. Moreover, supporting younger individuals results a more lasting impact, because it exerts its effect over a longer period of the life span. However, very young and very old individuals are more vulnerable to damages of reproductive value, like diseases or neglect, and therefore when benefits of altruism are significant, very old and very young individuals are less likely to receive help. On the other hand, if the age of puberty is close, or already began, the likelihood to receive help increases. Those of intermediate age are the most likely to receive help from relatives, because their contribution to current reproduction is the highest. Therefore, in life or death situations, the probability of kin altruism is curvilinear with the age of the recipient, but in everyday situations (when benefits of altruism are nearly 0) this correspondence reverses and aid flows to the youngest and oldest individuals (Burnstein et al. 1994). Although, helping relatives with limited reproductive value has moderate direct benefits, but it advertise our generosity, which can enhance the likelihood to get help from others (Zahavi and Zahavi 1997).

Status and Resources of the Recipient

In the case of differences in access to resources, helping is less costly for high-status individuals, thus the cost-benefit ratio of altruism is differing according to the resources available for the individual. Therefore, individuals can use their resources to manipulate others, thus wealth can lead to receiving more help but only under certain circumstances: in life or death situations, altruists do not discriminate between close kin according their status or resources, but they do in relation to distant kin. For example, high-status siblings receive help as likely as low-status siblings,

while wealthy cousins get help more often than less wealthy ones (Burnstein et al. 1994).

Physical Status of the Recipient

Numerous physical features can affect reproductive success through influencing attractiveness, for example, male height, which is associated with reproductive success (Nettle 2002). Another visible and significant factor is weight: both men and women prefer mates who are of average weight over thin or obese mates. Weight affects the reproductive functions of both men and women; therefore, it has a significant impact on the reproductive success of men and women. Women, who are excessively thin or overweight bear difficulties with their fertility. Underweight men display a decreased sperm count, whereas overweight is associated with lower levels of testosterone in men (see Fitzgerald and Colarelli 2009). In addition, there are several more, persistent physical health indicators (e.g., deformity or dysmorphism) which also influence kin altruism (see introduction of this section). Altruists evaluate the apparent health status of the recipient, and in life or death situations they tend to favor healthy kin over those poor in health, but in everyday situations this effect is reversed and altruists prefer relatives in poor health over healthy relatives (Burnstein et al. 1994).

Mental Health of the Recipient

More or less apparent reproductive limitations are mental disorders or problems in everyday mental functioning. Psychological problems can impair reproductive success, for example, depression (and many other psychological disorders) is associated with decreased sexual motivation or limited social functioning. These characteristics are less appealing for mates, thus helping kin with mental disorder produces a lower fitness payoff than helping kin who are not mentally ill. Moreover, individuals with mental illness are presumably less altruistic or cooperative, thus helping these people is likely to remain unrequited (see Fitzgerald and Colarelli 2009).

Sexuality and Reproductive Value

If an individual engage in sexual activities without reproductive possibilities, it is a sexual reproductive limitation. For example, as mentioned above, homosexuality (and to a lesser extent, bisexuality) is a behavior which is associated with a decreased probability to reproduce offspring. Sexual orientation is less conspicuous and not necessarily rigorous reproductive limitation since homosexuals are physiologically capable of reproducing (see Fitzgerald and Colarelli 2009).

Conclusion

In accordance with Hamilton's inclusive fitness theory, assessing cost-benefit ratio of helping involves proximate mechanisms to evaluate the reproductive value of the recipient. Recipient's handicap in reproduction can lead to a less advantageous return to fitness of the helper, hence altruists have to be able to take these limitations into account. Accordingly, individuals are less likely to help those, with a limited reproductive potential. However, there are many different forms of reproductive limitations, which may have different impact on reproductive value of the individual. In good agreement with this notion, empirical evidence showed that people are more willing to risk their lives to save a relative with a temporary reproductive limitation than a relative with more persistent limitation (Fitzgerald and Colarelli 2009).

Definition

Evolutionary theory predicts that when all else is equal, individuals will help their closely related relatives more than their distantly related relatives.

Introduction

Humans are prosocial species and typically provide help to one another. The term help can be defined as active and voluntary acts, including the transfer of any resources (e.g., time, money, material) from one individual to another. In evolutionary studies, contact and emotional closeness are often used as proxies for help because they tend to strongly correlate with several forms of support. According to kin selection theory, with all other things being equal, the likelihood of providing help should correspond to the degree with which individuals are related to each other and individuals are predicted to provide more help to their closely related kin than their distantly related kin (Hamilton 1964).

Empirical Evidence

On average, individuals share 50% of their genes with their parents, children, and full-siblings; 25% with half-siblings, grandparents, grandchildren, nieces, aunts, and uncles; and 12.5% with their great grandparents, great grandchildren, and first cousins. An abundant amount of empirical evidence shows that individuals tend to prefer kin over non-kin and close kin over more distant relatives (Salmon and Shackelford 2011). For instance, individuals provide more help and are more willing to make sacrifices if the beneficiary is a close relative and the readiness to help decreases with the degree of relatedness (Burnstein 2005; Madsen et al. 2007).

The exclusion of all other things besides the degree of relatedness is difficult because all else is never equal in human populations, meaning that several factors can affect the conditions under which helping takes place. However, different variations of sibling and twin relationships provide a research frame where all other things are closer to equal, but the genetic relatedness varies. Although individuals share an average of 50% of their genes with their full-siblings, the relatedness is only 25% between half-siblings. Moreover, dizygotic twins' relatedness is equivalent to full-siblings, but monozygotic twins are genetically identical.

Research on family relationships shows that the sibling ties are stronger between full-siblings than half-siblings and that the degree of relatedness predicts interactions and support between siblings (Pollet and Hoben 2011; Tanskanen and Danielsbacka 2014). A twin study, where different twin-pairs played the prisoners' dilemma game, found that identical twins were noticeably more cooperative with each other than other twin-pairs (Segal and Hershberger 1999). Furthermore, identical twins are also "genetic parents" of their co-twin's children, while dizygotic twins have customary relatedness to their nephews and nieces. A prior study found that monozygotic twin aunts and uncles expressed greater social closeness and gave more gifts to their nieces and nephews than dizygotic twin aunts and uncles (Segal and Marelich 2011).

Conclusion

Prior empirical studies have shown that individuals tend to favor their close kin over more distant kin and that the likelihood of providing help is associated with the relatedness of the individuals. These findings are consistent with the kin selection theory.

Definition

Heritability is the statistical metric that estimates the relative influence of genetic variation (measured as genetic variance) on phenotypic variation (phenotypic variance), relative to the influence of environmental differences (environmental variance).

Introduction

Heritability is a statistical parameter that is often used in discussions of genetic causation and the nature versus nurture debate. The heritability of a trait, represented by either H^2 (for broad heritability) or h^2 (for narrow heritability) is between 0 and 1. Traits with a high heritability are generally seen as genetically influenced, and those with a low heritability as environmentally caused (Lynch and Bourrat 2017).

The heritability concept most often invoked in psychological science is broad sense heritability. Broad sense heritability estimates the proportion of phenotypic variance (V_P) that can be accounted for by genetic variance (V_G), relative to the influence of environmental variance (V_E):

$$H^2 = \frac{V_G}{V_P} \quad (1)$$

$$V_P = V_G + V_E \quad (2)$$

Narrow sense heritability (h^2) is an alternative heritability measure which is primarily used in

breeding experiments by quantitative geneticists using animal models. It is concerned only with additive genetic effects (V_A), as these are reliably transmitted between generations. This is opposed to other kinds of genetic effects like dominance and epistasis (V_{D+I}), which encompass gene–gene interactions.

$$h^2 = \frac{V_A}{V_P} \quad (3)$$

$$V_P = V_A + V_{D+I} + V_E \quad (4)$$

Knowledge of h^2 allows one to forecast the adaptive potential of a given trait within a population, using the breeder's equation (Lush 1937). Usually these kinds of estimates are confined to traits in agricultural animals such as body weight, milk yield, life span, fecundity, and litter size (Falconer and McKay 1996).

Human research is less concerned about the adaptive potential of traits, and more interested in the sources of trait variation. Because of this, broad sense heritability is used, as it encompasses the total genetic contribution to the trait of interest. In order to calculate heritability, phenotypic data is collected from individuals who share a common family environment, and are genetically related to varying degrees. As environments are assumed not to vary between individuals in a family environment, the phenotypic similarities observed between parents and their children, or between siblings (especially twins), are assessed in light of their degree of genetic relatedness. See ► “Heritability” and ► “Twin Studies” for details.

Populations and Individuals

Heritability is a population-level parameter, and cannot be used to make causal inferences about individuals. For example, the heritability of height is ≈ 0.8 in most human populations. This means that if you lined up a population in accordance to their height, and wanted to know what accounted for differences in stature – you would find that environmental differences between individuals were largely unrelated to height differences, and

that genetic differences were associated with differences in height.

A heritability of 0.8 does *not* mean that only 80% of people have their height genetically influenced. It also does not mean that a given individual has 80% of their height genetically influenced, such that an individual who is 165 cm tall can attribute 132 cm to their genes.

At an individual level, both genes and environment are causally necessary for the production of phenotypes, and assigning values of relative causal importance to each is incoherent. Keller (2010) illustrates this with an analogy. Imagine two individuals, Billy and Suzy, who want to fill a bucket of water. Suzy holds a hose to the bucket, while Billy turns on the tap. Once the bucket is full, one could ask: “How much of the water is due to Billy’s contributions, and how much to Suzy’s?” The example is meant to illustrate that this question does not make sense, as partitioning causes in this case is not possible. Both the hose-holding and the turning of the tap are required to fill the bucket, and it is not possible to assess “how much” each caused the bucket to fill, relative to the other.

The Utility of Heritability Estimates

In addition to the pure explanatory utility of heritability estimates, broad-sense estimates can be used as a tool to investigate the causes of phenotypic variation in detail. For example, they may be used as justification for the search for genetic markers which are the first step of genetic mapping, and can lead to the isolation of candidate genes via methods such as genome-wide association studies.

Broad heritability estimates can also be used to estimate and predict the phenotypes of families and offspring, including complex diseases and behaviors. This information can be utilized for preventative procedures and genetic counselling strategies, as well as to provide extra intervention and support for those who may be genetically susceptible to undesirable phenotypic variants.

The heritability of a trait has also been invoked to discuss broader philosophical issues such as

free will and moral responsibility. For instance, Kaebnick (2006) raises the question: If no environmental interventions (that have yet been studied) seem able to alter the V_P of a trait, how responsible are individuals possessing a certain variant? Kaebnick believes that heritability analyzes help to inform, or at least introduce, some of these broader philosophical questions and should be considered by ethicists. Others such as Parens et al. (2006) have similarly theorized that knowledge about the heritability of a trait can impact on individual feelings of blame, responsibility, and human identity.

Heritability of Psychological Traits

One of Eric Turkheimer’s (2000) three laws of behavior genetics is that all behavioral traits are heritable. This is also true in the study of personality, which indicates that all personality traits are heritable to some degree (Bratko et al. 2017). Studies of personality using the five-factor model (extraversion, agreeableness, conscientiousness, neuroticism, and openness for experience) have yielded significant heritabilities (Power and Pluess 2015), as well as other models of personality such as Eysenck’s PEN (psychoticism, extraversion, and neuroticism), and Tellegen’s (positive affect, negative affect, and constraint) (Bratko et al. 2017). Overall, personality differences have a heritability estimate around 0.40, meaning that 40% of the variance is due to genetic differences, and 60% due to environmental influences (Bratko et al. 2017).

Intelligence is another trait of interest to psychologists. It was one of the first traits to be analyzed using heritability and is to date the most studied phenotype in behavior genetics. The heritability of intelligence is estimated to be 0.5–0.8 (Plomin and Spinath 2004). However, these estimates have been questioned due to phenomena such as the Flynn effect (Flynn 1984) which documents the rise in IQ test performance over generational time scales. While the IQ scores of a population reliably trend towards a normal distribution, the median raw scores of later generations are higher than those of earlier ones,

resulting in a continual re-adjustment raw scores, averaging a 3 point per decade adjustment (Flynn 1984). Another piece of evidence that indicates a significant environment influence on intelligence is observed IQ gains through adoption into higher socioeconomic (SES) homes, as well as through migration into higher SES countries (Sauce and Matzel 2018).

Mental illnesses and disorders have also gained a lot of attention in heritability studies. For example, schizophrenia has a $H^2 = 0.79$ (Hilker et al. 2018), unipolar depression $H^2 = 0.37$ (Sullivan et al. 2000), bipolar disorder $0.71 \leq H^2 \leq 0.77$ (Edvardsen et al. 2008), and Autism spectrum disorder $0.64 \leq H^2 \leq 0.91$ (Tick et al. 2016). Some of these results have been criticized on the grounds of nonadditive effects biasing heritability estimates. These are discussed below.

Nonadditivity

Standard models of heritability assume additivity of genetic and environmental variance. This means that phenotypic variance can be calculated as the sum of genetic and environmental variances as two independent variables. However, empirical evidence suggests that genes and environments interact nonadditively for generating trait differences. This can happen in two ways. The first is gene-environment interaction (GxE), which occurs when the effects of genotypes are differentially expressed depending upon their environment. Likewise, environmental influences act differentially depending upon the genotype of an individual (Tabery 2014). For example, there is a genetic interaction with cannabis usage for development of schizophreniform psychosis. Individuals with a certain variant of the *COMT* gene are more likely to develop psychosis when exposed to cannabis, compared to those with a different gene variant (Caspi et al. 2005).

If GxE effects are not detected, then the resulting heritability estimate will be incorrect, as it is using an erroneous model of variance contributions. When they are detected, they can

be accounted for by updating the heritability model to include an interaction effect:

$$V_P = V_G + V_E + V_{G \times E} + r_{GE} \quad (5)$$

Even if no GxEs are detected, or if they are detected and adjusted for in a nonadditive model (Eq. 5), they still pose a problem for the extrapolation-worthiness of heritability estimates. GxE occurs when genetic differences make a difference to phenotypes in different ways depending upon the environments experienced by the population under study. This makes it difficult to make general claims about the genetic causation of traits across populations. This problem was first identified by Lewontin (1974), who argued that GxEs are problematic for heritability estimates even in cases where none have been identified. Although genes and environments may behave additively in one population, resulting in a particular H^2 , that does not rule out that there could be interactions in different, unstudied environments in unobserved populations. This problem has led some to reject the utility of heritability estimates all together.

The second form of nonadditivity is gene environment correlation (r_{GE}). This occurs when certain genotypes and certain environments are more likely to be found together, and so at a population level genetic variance and environmental variance become associated. There are three forms of r_{GE} (Plomin et al. 1977). The first is passive r_{GE} , which occurs when parents pass on associated genetic and environmental influences to their children. For instance, children of avid readers might inherit genes which provide good comprehension skills, as well as environments filled with many books. Thus, both genetic and environmental influences on reading ability are correlated within the population. Passive r_{GE} s can be isolated using adoption studies, or by controlling for potential correlated environments in study designs. Active r_{GE} s occur when certain genes predispose an individual to seek out certain developmental environments. In this case, the environmental exposure is an indirect effect of genotype, and so genes and environments are correlated at the population

level. For example, bright children with a genetic advantage for academic study may, thanks in part to their genes, seek out more stimulating environments, further advancing their academic performance. A third form of rGE is reactive cases. These occur when individuals experience certain environments because of the way society reacts to some aspect of a genetically influenced genotype. This is thought to occur in problematic society-based reactions to different racial groups. Individuals possess genes which express themselves in physiological traits such as skin color, and because of these traits, those individuals are subject to harassment, or deprived of environmental resources, compared to counterparts with a different genetic background.

Active and reactive rGEs are difficult to detect in the study of heritability, and there is debate as to whether or not active cases should be included as part of the additive effects of V_G (Lynch 2017). Evidence for active and reactive rGEs comes from the heritability of environmental variables, such as socioeconomic status, television viewing, and quality of social support (Plomin and Bergeman 1991). Rutter, Moffitt and Caspi (2006) and Rutter and Silberg (2002) have proposed that rGE contribute significantly to the heritability of psychiatric disorders. For instance, aggressively prone offspring are likely to promote harsher treatment from others, compounding their development along a psychiatric trajectory. This work has been extended by Jaffee and Price (2007) who have identified particular allelic variations and their associations with environments, such as parental rejection. These associations are then predictive of later psychiatric illness, indicating that genetic variation may account rGE with parental engagement. Meek et al. (2013) have suggested that heritability estimates for autism may also be largely accounted for by active and reactive rGEs. Children who begin as mildly autistic are likely to select environments lacking in social stimuli (active rGE), and others around them can react to them in a way which compounds both their autistic phenotype (reactive rGE) and their subsequent environmental selection (further compounding the active rGE pathway).

Conclusion

Heritability is a statistical parameter that estimates the influence of genetic variation on phenotypic variation, relative to environmental variation. Broad heritability (H^2) is the most widely used statistic in the human sciences, and is used to explain the causes of trait differences at a population level. Many psychiatric disorders, personality differences, human abilities, and behaviors have significant heritabilities. These results can be used to understand the causes of trait differences in a population; however, causal claims about relative influences of genes and the environment cannot be made about individuals using heritability results as heritability is strictly a population-level parameter. The population relativity of H^2 has led to some criticisms of the utility of the estimates. In particular, the existence of gene-environment interactions – both within actual and hypothetical populations – is problematic for extrapolating heritability results. Additionally, gene-environment correlations undermine the additive model used for heritability estimates, and are difficult to study and control for. There is growing evidence that gene-environment correlations account for some of the estimated heritability for psychiatric traits.

Definition

“Heroic rescue” occurs when an individual places himself/herself at risk to save another person in a life-threatening emergency situation.

Introduction

When defining altruism, social scientists usually focus on the intentions of the altruist, and their research has traditionally attempted to isolate the situational factors that determine when people will behave altruistically. Five decades of research have identified the importance of such factors as empathy, rewards, emotional states, social norms, and the number of bystanders in influencing helping behavior. Social science models of altruism do not address the question of why basic motives such as empathy and various situational factors came to be so important. In fact, even most social psychologists continue to study altruism and other social behaviors with little reference to the origins and ultimate functions of altruism, which have been the primary focus for evolutionary psychologists.

Altruism has always been a thorny issue for evolutionary theorists; the idea that an organism would engage in a behavior that comes at a great personal cost and seems to benefit only other individuals was difficult to explain through the basic principles of natural selection. Over time, however, several theories have been developed that may explain such behavior, with each theoretical perspective offering a more suitable explanation for some types of altruism than for others (McAndrew 2002).

Differentiating Heroic Behavior from Other Forms of Altruism

Heroic behavior is qualitatively different from other types of helping behavior. For example, there are many situations in which individuals help others who are not related to them: they loan money and personal belongings to friends, give rides to strangers who are hitchhiking, and go out

of their way to do favors for acquaintances who ask for help. Such acts, however, should not be described as “heroic,” if only because they do not pose any severe risks to the altruist. On the other hand, individuals may put themselves at great risk to save their children or other relatives during emergencies, or they may engage in long-term costly behavior that benefits family members. However, self-sacrificial acts performed for close kin are usually not described in everyday life as being “heroic” or even as “altruistic.” The word “heroism” is usually reserved for those behaviors in which the altruist puts him or herself at physical risk to rescue unrelated individuals who find themselves in a life-threatening situation.

Heroic Rescuing of Relatives

It was not until the concept of *inclusive fitness* was introduced by Hamilton (1964) that evolutionists had a satisfactory theoretical framework for discussing altruism.

Inclusive fitness is often referred to as *kin selection*, because according to this concept, natural selection favors behaviors that benefit others who share our genes, especially closely related kin. Hence, the mother who sacrifices her life so that her children survive may actually be engaging in a behavior that is genetically very adaptive, as the copies of her genes that reside in her children will in the long run lead to greater genetic fitness than if she alone had survived. Although the parent who rushes into a burning building or dives into an icy river to save one of his or her children is admired and the intense emotions driving such behavior are easily understood, the mantle of “hero” is not usually bestowed upon such individuals. The powerful impulse to rescue close kin from harm can most easily be understood through the lens of inclusive fitness and kin selection. Whether such dramatic helping of kin can properly be described as “heroic” is open to question.

The concept of kin selection is somewhat limited in that it cannot explain the whole range of altruistic behaviors observed in humans and other animals. For example, it cannot account for

altruistic acts aimed at other individuals known not to be genetic kin.

Heroic Rescuing of Friends

Reciprocal altruism (Trivers 1971) is defined as cooperative behavior among unrelated individuals that benefits everyone involved. Individual success at reciprocal altruism depends greatly on the ability to identify and cooperate with others who are good exchange partners and to identify and avoid those who are cheaters. Because humans are a supremely social species, the selection pressures faced by early humans in this regard must have been profound. It would have been evolutionary suicide to consistently behave in a selfless, altruistic manner toward unrelated individuals who took as much as they could get while offering little in return. Consequently, it should not be surprising that research has confirmed that humans are primed to recognize true altruists as well as cheaters and to deal with these individuals appropriately (Brown and Moore 2000; Mealey et al. 1996). Reciprocal altruism probably offers the best explanation for heroic rescuing among friends. Friendships are established after individuals have arrived at a mutually satisfying and reliable pattern of equitable exchange. To put one's self at risk to rescue a friend may in fact be something of an obligation but also something that the helper may expect to be repaid in some manner during a future time of need.

Heroic Rescuing of Strangers

Inclusive fitness convincingly explains sacrifice for family members, and reciprocal altruism allows an understanding of individuals who sacrifice for the benefit of unrelated others with whom they have an ongoing relationship. However, anyone who helps others and expects payback will not be thought of as a hero, and in spectacular life-saving acts of heroism, it is clear that no adequate payback could really be possible anyway. It is in the arena of the rescuing of strangers that the term "heroism" is most aptly applied.

The best explanation for the heroic rescuing of strangers may be found in *Costly Signaling Theory* (CST) (Bliege Bird and Smith 2005; Boone 1998; Grafen 1990; McAndrew 2002; Roberts 1998; Zahavi 1977). CST suggests that conspicuous self-sacrificial heroism may be a way for individuals to advertise desirable personal traits. This might increase the likelihood that they will be chosen as a mate or an ally and it might also position them for access to future status and resources, even from individuals who were not direct beneficiaries of the heroic act. For a costly signal to be effective, it must honestly convey valuable information about the individual sending the signal, and it must be impossible to fake.

Evolutionary psychologists believe that even apparently selfless impulses such as the heroic rescuing of strangers must provide some adaptive advantage for individuals; otherwise, such behaviors would have been strongly selected against. Many studies demonstrate that people who sacrifice for the group by engaging in costly activities do in fact achieve elevated social status, respect, and recognition as a result of their public selflessness (Bereczkei et al. 2010; Hardy and Van Vugt 2006; McAndrew and Perilloux 2012a, b; Nowak and Sigmund 2005; Sylwester and Roberts 2010; Van Vugt and Hardy 2010; Willer 2009). No researchers suggest that heroes consciously sit down and calculate all of the benefits that will come their way if they survive the heroic action. Rather, it is thought that such impulses have been selected for because heroic behavior has provided competitive advantages for men throughout human history.

Sex Differences in Heroic Rescuing

There are certainly many examples of women behaving heroically, but physically risky, self-sacrificial heroism is commonly perceived as a stereotypically male behavior (Griskevicius et al. 2007; Iredale and Van Vugt 2009; Lyons 2005). If self-sacrificial altruistic behavior is in fact a "male thing," it should be most likely to occur when males show off and compete directly with each other for status (and ultimately for

mating opportunities). It has been established that altruistic male behavior is most effective if it takes the form of risky heroism, which displays courage and strength (Farthing 2005; Griskevicius et al. 2007; Kelly and Dunbar 2001; Sylwester and Pawlowoski 2011). Also, males are more likely to display altruism in the presence of an attractive member of the opposite sex; the same does not hold true for females (Farrelly et al. 2007; Iredale et al. 2008). This idea has clearly been around for quite some time, as illustrated by a quote from the Sioux warrior Rain in the Face. In describing the effect that the presence of women in a war party has on the male warriors, he said “when there is a woman in the charge, it causes the warriors to vie with one another in displaying their valor” (Philbrick 2010, p. 179).

The *Challenge Hypothesis* developed by Wingfield et al. (1990) provides a framework for predicting the circumstances under which male “showing off” via conspicuous self-sacrifice will be especially likely. According to this hypothesis, physiological changes such as a rise in testosterone occur in response to threats to a male’s status or the imminent threat of male-male competition, facilitating whatever competitive behaviors are necessary to meet the challenge. Thus, showing off may pay off best for a man when there is another man present that one can look superior to. Consistent with the aforementioned hypotheses, McAndrew and Perilloux (2012a, b) have confirmed that self-sacrificial male behavior is most likely to occur when females *and* another male are present.

War Heroism

War is a male activity. Organized fighting and killing by groups of women against other groups of women has simply not existed at any point in human history, and given the wide range of diversity to be found across human cultures, the consistency with which males are the organizers and perpetrators of group conflict has led many scholars to conclude that the male propensity for group violence is rooted in more than the learning of culturally prescribed gender roles.

Evolutionary psychologists have studied war and conflict with the assumption that a predisposition for warfare has evolved in males because it has historically enhanced their reproductive success. Hence, the origins of warfare and war heroism can ultimately be found in the competition between males for status and access to women.

Sexual competition for mates has always been more intense among males than among females, especially in the polygamous societies that appear to have been typical in the prehistoric human world. The stakes were very high for men in this environment, as the winners of this competition would come away with the greatest number of women (and the most desirable women). The losers ran the risk of genetic annihilation by their failure to successfully win the status and resources necessary to attract mates. Historically, powerful men have always enjoyed greater sexual access to women than men lower in the pecking order, and violence, including war, can often be traced to this grim struggle for status and mates among men.

Violence committed against the right people at the right time has commonly been a ticket to social success for men. For example, among the Yanomamo of South America, men who had killed other men, especially during wars and skirmishes with other villages, acquired significantly more wives than men who had not yet killed anyone (Chagnon 2013). Because having killed someone in war was often good for one’s reputation, many societies developed ceremonies for recognizing such accomplishments. In modern societies, these take the form of prestigious awards such as the Congressional Medal of Honor in the United States, and many countries have national holidays to celebrate the heroism of those who have fought and/or died in wars.

War heroes are held in such high esteem because they seem to act in a noble and virtuous manner, setting aside any thoughts of their own well-being for the good of their group or tribe, but conspicuous war heroism may also be a way for men to enhance their long-term reproductive fitness. Dutch psychologist Mark Van Vugt (2007) has proposed the *Male-Warrior Hypothesis* as a way of explaining why men show stronger group identification and more cooperation with in-group

members than do women during times of threat from outside groups. His theory suggests that men have evolved a predisposition to engage in collective cooperative aggression against out-groups, a tendency that has likely been strongly reinforced through culture traditions and socialization.

A team of European psychologists (Rusch et al. 2015) explored the proposition that war provides an arena for men to compete and impress both their male rivals and females who might be potential mates. In one study, they found that 464 American men who had won the Medal of Honor during World War II eventually had more children than other US service men who had not been so heroically distinguished. This is consistent with the idea that heroism gets rewarded with greater reproductive success. In a second study, 92 women rated the sexual attractiveness of men who had behaved heroically in war as being higher than that of soldiers who had served but not been identified as heroes. Tellingly, women did not show this increased attraction toward men who had behaved heroically in sports or business situations. A third study revealed that behaving heroically in war does not increase the attractiveness of female war heroes to men. In summary, heroism in time of war is sexier than any other kind of heroism, but only for men.

Young men are particularly concerned with status and heroic opportunities for sound evolutionary reasons. In early human societies, competitive success or failure in early adulthood determined a man's standing in a social group for the rest of his life. It wasn't possible to simply hit the "reset" button and join another group, so what happened during the teen years mattered a lot. For this reason, high-risk competition between young males provided an opportunity for "showing off" the abilities needed to acquire resources, exhibit strength, and meet any challenges to one's status. Consequently, heroic or even recklessly daredevil behavior was rewarded with status and respect – assuming, of course, that the young man survived the ordeal. Displaying heroism in time of war was a primary way of accomplishing these goals. Hence, it should not be surprising that historical data confirm that the concentration of young men in a population is one

of the best predictors of when a society is most likely to go to war.

War is costly and risky, and for male psychology to have evolved a predisposition for going to war, several essential conditions must be met. John Tooby and Leda Cosmides (2010) have identified four conditions that would be particularly important. First of all, successful soldiers must have greater sexual access to women than non-combatants. Secondly, coalitions of fighters must believe that they will be victorious. Thirdly, the rewards that each warrior receives must be proportionate to the risks he has taken and the importance of his contributions. In other words, cheaters should never prosper. And finally, men going to war must not know for sure who will live and who will die; there must be a protective "veil of ignorance."

Conclusion

High-risk "rescuing" behavior is most appropriately described as heroic when it involves the rescuing of individuals with whom one shares neither genes nor an ongoing cooperative relationship. There is evidence that an impulse toward physically risky heroic rescuing behavior has been more strongly selected for in males than in females. These impulses serve a noble function when they result in altruistic behavior, but these same competitive status-seeking drives are also a component of war and other aggression actions.

Heuristics

Heuristics are strategies that ignore information in order to make faster decisions. Traditional theories of decision-making (including the highly influential “heuristics-and-biases framework”; Tversky and Kahneman 1974) suggest that heuristics are suboptimal shortcuts that lead to systematic errors, trading accuracy for speed. These frameworks imply that heuristics are irrational and that decision-makers would be better off if they could avoid heuristics altogether.

In reality, heuristics are extremely sensible, having proven to be reliable tools for successfully navigating diverse situations of uncertainty (Gigerenzer et al. 1999, 2011; Gigerenzer and Gaissmaier 2011). For example, Ortmann et al. (2008) observed that, on average, stock portfolios created using the *recognition heuristic* (i.e., if one option is recognized and the other is not, choose the recognized option) outperformed unplanned portfolios, the market, managed funds, and stock experts. Heuristics are not only useful but, perhaps more importantly, they are efficient; heuristics are both fast and frugal, limiting the amount of information processed while giving comparable (if not superior) results than their more complex counterparts. Consequently, heuristics make perfect tools for situations of bounded rationality, scenarios where decision-makers have limited capacities and resources. This understanding stands in stark contrast to traditional economic

approaches, which assume decision-makers are able to invest unlimited resources in a given problem, making them untenably costly and thus unrealistic cognitive strategies.

Ecological Rationality

Ecological rationality describes robust fit of cognitive mechanisms that have evolved to solve recurrent problems in regularly encountered environments. Fast and frugal heuristics meet the criteria of ecological rationality because they reflect speed and efficiency of cognitive processing; they also reflect robust sensitivity to the structure of decision-making environments. Simon (1990) elegantly illustrated the concept of ecological rationality with a scissor analogy: Human behavior is shaped by the two interdependent blades of (1) the task environment and (2) the actor's ability to carry out a given strategy. Heuristics are useful because they are typically within the limit of the actor's capabilities, but only in certain task environments. Heuristics are also typically more robust than other decision-making tools. They are not overfitted to a single environment and can therefore be utilized in multiple contexts. Heuristics are also very specific in terms of inputs, making dealing with ambiguous contexts more tenable as they do not require having to search through all the data, just the specific criteria outlined.

Building Blocks of Heuristics

Gigerenzer et al. (1999) proposed three main building blocks of heuristics: (1) search rules, (2) stopping rules, and (3) decision rules. Search rules dictate how decision-makers search possible options. Stopping rules detail the circumstances under which the search will stop. Finally, decision rules outline how the final decision is reached.

For example, when deciding what to eat, people appear to use a *lexicographic heuristic*, tending to consider only their most important criteria (e.g., taste) instead of taking a weighted sum of all the possible criteria (e.g., taste plus

price, texture, nutrition content, convenience, ethical concerns, among others; Scheibehenne et al. 2007). In this instance, the individual dining searches through the criteria (search rule). They then find the most important criteria (stopping rule). Finally, the individual chooses the option that rates highest on that criteria (decision rule). These three simple rules outline a process that is fast, frugal, and efficient.

Examples of Heuristics

Heuristics can be used in a variety of settings, including physical, social, and group situations. For example, baseball players use the *gaze heuristic* to catch a ball flying through the air, maintaining a constant optical angle between themselves and the ball, rather than calculating the ball's trajectory in three-dimensional space (McLeod and Dienes 1996). Certain animals also use the gaze heuristic to catch prey or to pursue mates (Gigerenzer 2007; Shaffer et al. 2004).

Heuristics can also be used in social situations. Axelrod (1981) suggested that individuals often use a heuristic "tit-for-tat" strategy in cooperative situations. In utilizing this strategy, individuals initially choose to cooperate. After that, decision-makers simply replicate their partner's most recent choice: if the other person defects, the decision-maker defects. If their partner cooperates, the decision-maker cooperates. This simple strategy leads to a high chance of avoiding potentially harmful social situations, but is also extremely robust and efficient to apply.

Groups also appear to use heuristics. For example, Gonzales et al. (2017) observed that football teams make in-game decisions consistent with *risk-sensitivity theory*, which hypothesizes that decision-makers simply chose riskier options when less risky options are unable to meet a salient need (reviewed in Mishra 2014). Teams were shown to choose the riskier option of passing more frequently whenever running (the less risky option) was unlikely to attain a salient goal (i.e., getting a first down or winning the game).

Heuristics provide a useful tool for navigating a world full of uncertainty. When used in the

appropriate situation, a heuristic can be a mechanism that allows a decision-maker to make good decisions without allocating excessive resources to solving the problem. Traditional approaches to understanding decision-making ignore necessary constraints of human cognition (i.e., they reflect “unbounded” rationality as opposed to “bounded” rationality). However, an evolutionary account requires that decision-making mechanisms be fast, frugal, and robustly fitted to environments of decision-making, thus highlighting the importance of heuristics in decision-making.

Hierarchical Climbing

Definition

The Webster Dictionary defines it as “the classification of a group of people according to ability or to economic, social, or professional standing,” or in simple terms, it can be referred to as “a graded or ranked series.” Hierarchy is a social order in which members of an organization are arranged according to their relative authority. This organization can be a simple unit such as a corporate institute or something as complex as the society. Hierarchical climbing in simple terms can be referred to as the process of moving up the hierarchy, up the ranks to reach a higher level which could be in terms of designation, status, money, or power.

Introduction

When you ask a child what he aspires to be in the future, the most frequent answer by any child would be “I want to be rich and successful.” If

further asked to elaborate, they will choose professions that rely on power, fame, or high-ranking officials. When you ask adults what they aspire to be in the future, replies would range from becoming the head of the department, a professor, and a chief executive officer depending on the job description currently with a bigger pay grade. Hearing these answers, one can wonder that all humans are basically similar and want the same things in life to feel content. Success is seen in the form of high-ranking jobs, money, status, and power. So how does this relate with hierarchy? Darwin proved “survival of the fittest.” The same is applicable now to humans as well. If one wants to survive, what does one have to do? Have a secure source of living, a constant, dependable job – a job which is hopefully high ranking. And here, the concept of hierarchy fits in. Hierarchy is a common property of all organizations as seen in almost all biological as well as man-made establishments (Mengistu et al. 2016). Hierarchical climbing is a concept in institutional dynamics and social network. It provides a framework within which individuals can tap their potential best. This increases their productivity, and they become more central to the society. Institutions can be seen as rules that are forced on individuals, or they can be thought of as a group of people with a common belief system (Brousseau and Raynaud 2011). It relates to our society, our offices, our institutions, and even our very own homes. It is closely associated with the concept of power, social status, and standing. This article covers the concept of hierarchical climbing in detail, the aspects related to evolution, the need, and the significance.

Evolutionary Aspects

Hierarchical climbing is not just a concept in institutional dynamics. It is a basic principle in biology and an important reason how evolution has led to the development of more complex organisms. Hierarchy promotes more stability and tenacity in systems and encourages versatility. Hierarchical evolution in biological systems arises out of natural selection: direct or indirect (Mengistu et al. 2016). Hierarchy and leadership

originally came into being to solve problems of coordination in species living in groups. Among humans, it was adapted according to our needs of solving conflicts and maintaining relations among different groups. The reason behind the emergence of hierarchy in social and corporate systems can be best explained by limited resource at disposal or by local interactions. While competing for the same resources, individuals in well-led groups are found to be more efficient. So cost of connections is a driving factor in man-made networks such as the Internet and other corporate institutions (Mengistu et al. 2016). Initially, institutions are “local and voluntary”; gradually, they evolve into more “generic and mandatory” ones. There are two distinct phases in the development of the institutional system – its environment and arrangement. Institutional environment forms the basis of interactions among the agents of a particular institution, whereas arrangement refers to contractual agreements between them. There are certain rules that are mandatory because either they are state-enforced or they represent the cultural norms of that society. New local rules are made after mutual agreements among agents. Over the course of time, these rules tend to be more widely accepted as a result of which they become nonnegotiable and mandatory. This is how evolution of an institution occurs. The best example of the above phenomenon was seen among the stockbrokers of New York in the 1800s. A small group of dealers started to abide a set of informal yet binding set of rules. This group grew in number slowly which made it all the more attractive. Being a part of this group had its own perks, for example, more partners and trustworthy records. Stockbrokers in other states formed similar systems with comparable benefits in order to compete with them. As individual agents had a plethora of options on their plates, it gave rise to competition and a refinement of the institutional network. This development of a common order in an institution is also beneficial in the sense that it supports division of labor (Brousseau and Raynaud 2011). So why do we need to climb this system, this ranking? What would we achieve? How will this affect our lives? Since we are young, what are we constantly pushed toward? To do well. First, it is the basic

academics, tests, and exams in our classes, then competitions which may be extracurricular, then competitive or entrance exams, then jobs, then perfect partner, and the cycle goes on. Life is nothing short of a competition, and to win this said competition, one has to be successful. One has to be the highest-ranking official or the head. This constant rat race which individuals find themselves in is the driving force behind the need to climb, the need to move forward. As if one is not moving forward, then he is just stuck or moving backward and faces it, and no one wants that. This is just not the inner voice in our heads but what our society makes you feel. Let alone the society, if one is not out there achieving something, this voice can take shape of the people in our lives like parents and significant others. In order to push further, add fuel to the fire, and here comes in the concept of ego. One is made to face this reality and think, even if not needed, that they really are a failure. Is everyone around them and are they stuck in actual route? So a push becomes a shove, and an unnecessary need arises in the mind of the said individual to move forward – to move ahead in the pecking order. Rank up, as this is the only way one could find the lost respect in his family and his own eyes. This is then linked up with what will happen if one ranks up – the perks, the status, and the power. Everyone views their superiors in awe – if only they had the life they had, the car they drove, the house they lived in, the clothes, and jewelry they wear. What would happen if that all could be theirs? How the current scenario would change? In this process, one may even imitate his superiors, to feel at the same place as them, the same mentality, to form a common bond. If one ranks up, the social standing and status would also rank up, improving his presence or influence per say. Here, the concept of status which can be explained as “the extent to which an individual or group is respected or admired by others” could be viewed as the benefit one would achieve as most individuals are driven by power and greed, with using hierarchical climbing as a stepping stone to achieve their goals and agendas. In this process, it works by the concept of positive reinforcement. One could reap an award, and for this to occur, one has to move up in order, which could happen if one

works hard consistently. The same concept can be further applied to power, as with a higher pecking order comes in more responsibility and power. The road to success is simple, the path of climbing up the hierarchy of the said institution. Hierarchical climbing as a concept cannot be limited to the workspaces, offices, and restaurants but also in our households. How does it apply to a household? It may seem farfetched or even comical, but the resemblance is uncanny. Running a perfect household requires planning, division of tasks, and complete execution along with someone to look over the swift functioning. Now if, per say, every individual carrying out individual tasks are at the same rank, it may lead to quarrels and constant friction, with one trying to overpower the others. This would in turn lead to a cascade of fights, eventually breaking down a well-functioning machine. So in order to having a smoothly functioning system, there is a need to delineate duties, assign them, and make sure that they are conducted in a proper manner. For this to happen in a sustainable manner, a rank is needed. There will be helps doing the menial jobs, reporting to the housekeeper who in turn will try to ensure a smooth functioning and in return reporting to a particular member of the family. The drivers and watchmen will report to another member. And these will then report to the matriarch. This micromanaging not only helps in equal division of labor but also helps in having a check on all levels. As work is individualized, there tends to be less of overstepping by peers and fewer doubts and questions. And having a superior to report to, they tend to have a satisfaction that in case anything goes down, an option to fall upon will be present. This helps those on a lower rank to have faith in the system, that someone up there will help them, which further leads to the aspiration of moving forward, moving up the order.

Significance

Societal structure depends on the incentives provided to its members. The more these members strive to climb up the social ladder, the more the hierarchical system is reinforced. It works like a

feed-forward loop. Hierarchical model is a sophisticated model of the society in which every person attempts to strengthen his place in the society by trying to become as central as is possible. The basis of hierarchical climbing is organization. It clearly defines the position and the role a member plays in the institution and lays down the chain of command. It helps avoid any uncertainty in goal setting and the path taken to achieve that goal. The person's importance in the network is defined by his centrality. A disordered system creates chaos and confusion as the members struggle to find out with whom they should connect in order to attain a central position in the society (Bardoscia et al. 2013). In institutions requiring high interdependence such as the army or mountain climbing expeditions, the benefits of hierarchy are more pronounced. Individual incentives for high social status are enough to confer this property to the social network, even in the absence of explicit discrimination of particular groups (e.g., caste system or racial segregation) or preferential biases (e.g., hereditary rules). In addition the hierarchical state is more or less stable with reduced social mobility in the extreme sections of the hierarchy. More structured the hierarchy is, a lesser degree of mobility is seen. It is tempting to relate this to the pervasive empirical observation that more unequal societies tend to have lower intergenerational mobility. Wealth or political power is likely to contribute to reinforcing our results. Also, we show that the social climbing game admits a potential function, thereby allowing us to deploy techniques and concepts of statistical mechanics to understand the behavior of the system. The appearance of a social hierarchy in a system of *a priori* identical individuals is an example of a random breakdown of symmetry, in which the resulting ergodicity loss accounts for a reduced social mobility.

Practical Aspects

Hierarchy might as well be considered as a double-edged sword. It has the ability to bring out the best as well as the worst in an organization. Since social mobility has been found to be limited

at the extremes of social order, it brings about a feeling of psychological insecurity (Bardoscia et al. 2013). Members who are low down in the ladder of social ranking become hesitant of voicing their opinions. Quite often, they are dissuaded from doing so. Sometimes individuals avoid contributing with their opinions so as to avoid challenging the hierarchy. Functional accounts of hierarchy propose that hierarchy increases group coordination, whereas dysfunctional accounts claim that hierarchy impairs performance by preventing low-ranking team members from voicing their perspectives. When strong values of hierarchy are instilled in a group, it leads to a well-planned effort, but it can also stifle the voice of the lower-ranking members of the order in the face of adversity. It has been observed that institutions allowing lower-ranked team members to voice their concerns instilled in them a feeling of confidence. They were also able to identify any errors in their methods and could avoid any adverse repercussions of their decisions (Anicich et al. 2015). The hierarchical state is found to be more or less stable with minimal mobility in the extremes. Social mobility is highest in the middle class. More structured societies tend to exhibit lower social mobility. Social hierarchy stabilizes gradually giving rise to social elites that grow over time with wealth and power acting as strong influences.

Conclusion

Hierarchy is necessary so as to encourage people to tap their unmet potential as it encourages competition. Discrimination and development of power elites is detrimental to the social order as it defers the promotion of individuals higher in the social order according to their capabilities. Inequality is admissible if categorization is on the basis of capabilities rather than a result of discrimination (Bardoscia et al. 2013). All members of a society must have access to similar opportunities for growth and must be treated as equal. All in all, this strategy gives a base for not only our institutions but the society as well. This concept applies even on the grassroots level to the

simplest of organizations, for example, a small café serving coffee to the multinational companies with offices spanning the entire globe. History has been evidence enough that this concept helps in the smooth functioning of most and helps restore faith in it as well. It may not only lead to a formation of comradery with peers or individuals at the same level who experience the same hardships but also help in the formation of a two-way channel between different ranks, with each having a particular role to play, helping in the proper functioning. Although it may have a few disadvantages, these are outweighed by the advantages and the evidences. Further, the correlation with ranking up the scale for the opportunity to grasp a higher social standing and power substantiates the need for the same, establishing the practicality. Finally, it helps instill a belief, a hope for a better future, filled with infinite number of opportunities and doors as one moves up this hypothetical ladder to reach a gateway of endless benefits.

Definition

Individuals with higher socioeconomic status (SES) tend to be against the distribution of resources, aiming at securing advantages over others.

Introduction

Status emerged as an evolutionary solution consisting of the establishment of simple rules to avoid and resolve conflicts in hierarchical groups. In the environments of forage societies, acquisition and sharing of resources were key issues for the survival of individuals and groups. Thus, the process of cooperation and competition was a determinant of survival. Within social groups, these processes of exchange of resources could generate competition or hostility, culminating in conflicts between group members. To avoid this costly relationship, many species of primates have developed ways to minimize possible social conflict by imposing simple systems to determine access and control over scarce resources, such as the concept of status. In modern societies, individuals with high socioeconomic status (SES) tend to oppose resource redistribution. The explanation for this opposition to economic redistribution derives from adaptive cognitive and motivational mechanisms that were selected in the evolutionary process to solve resource allocation problems (Kurzban and Neuberg 2005; Sidanius and Kurzban 2013; Sznycer et al. 2017).

Redistribution and Status

In modern times, redistribution refers to the change in the distribution of resources in a population resulting from a political process. As in other decision-making processes, support for redistribution occurs through the processing of specialized computational systems of human cognitive architecture. It is necessary to understand the evolutionary origins of the motivational processes that result in opposition or support for redistribution. For example, among primates,

dominant males generally have more control over scarce resources, including partners, increasing the likelihood of reproductive success (e.g., greater chance of survival for offspring, more offspring; Kappeler and van Schaik 2002). The same is true for dominant females, as status positively affects their nutrition, which increases their likelihood of reproductive success. That is, resource management impacts on the survival and reproductive success of individuals, so sharing or distributing is an adaptive problem.

Differences in access, control, and redistribution of resources can motivate conflicts. Status and hierarchy relationships are dynamic, and disadvantaged groups can get organized to force redistribution of resources. In the same way, dominant groups or individuals can come together to secure their position within a social hierarchy. Then, status emerges as a strategy for hierarchical classification within groups, signaling access to social (individual or group) and economic resources. This strategy creates implicit social rules about the distribution of resources, with the function of avoiding or minimizing costs with competition and constant conflicts over scarce resources.

In modern societies, the socioeconomic status (SES) derives from this notion of status. Individuals with higher SES are those with higher levels of wealth, such as privileged access to income, education, and occupation. People with higher SES are less likely to support policies that redistribute wealth and have less favorable feelings toward economic redistribution (Brown-Iannuzzi et al. 2015). Humans balance prosocial motivations with self-promotion to deal with social hierarchy relationships (Petersen et al. 2012; Sznycer et al. 2017). Even in scenarios in which cooperative relationships are necessary for group survival, sharing arises only as a form of maintenance of the type of resource distribution. Cooperation through controlled resource distribution functions as a strategy for self-promotion and building alliances or coalitions (Kurzban and Neuberg 2005). Social badges, such as speech or dress code, are used to assess the extent to which others are expected to cooperate in promoting group interests. These cues act as markers that guide the selection of

alliances or coalitions by creating a behavioral expectation through the share of common social norms. Thus, individuals promote self-interest and, at the same time, reduce the social costs of coercive or dominant strategies through prosocial gestures.

Motivations for Redistribution

Humans have interacted with individuals with varying levels of access to resources or SES throughout evolution, and our motivational systems may have been naturally selected to deal with the challenges and opportunities arising from these social relationships. Therefore, the personal standpoint on the redistribution of income and wealth among human beings permeates often unnoticed aspects. For example, in men, physical strength shapes the support for redistribution (Petersen et al. 2013). Among men with lower SES, physical strength predicts support for redistribution and among men of higher SES, the opposite. This is probably because physical strength is a relevant aspect of the ability to fight. Individuals with higher fighting ability will tend to acquire or defend resources rather than less skillful competitors. As personal strength is irrelevant to compensate for economic policies in modern societies, one can conjecture that decision-making on redistribution is shaped by a psychology designed by evolution for small groups. Among human, relations of cooperation, such as sharing of resources, occur mainly between individuals with some degree of kinship. It commonly occurs as a partner attraction/retention strategy or to form/preserve status (White et al. 2013).

Our ancestors were constantly in social situations where they had to solve problems, among others, related to the distribution of resources. The human mind was designed by evolution to seek clues and to provide emotional responses to evolutionarily recurring challenges and opportunities regarding the social distribution of resources (Sznycer et al. 2017). For example, humans are more motivated to share when they are subject to chance-driven interruptions and less motivated

when they think they are being exploited by low-effort free riders. The motivation to share with nongenetically close individuals has evolved as a defense mechanism against opportunists, low-effort free riders. Petersen et al. (2012) found anger and compassion as the main motivators of these mechanisms. Encountering individuals who accept help without contributing, such as intentional avoidance of a productive effort (i.e., parasitic strategies), triggers anger and decreases support. The subjects' perceptions of the recipient's effort (e.g., search for work) regulate compassion and anger which in turn mediate views about well-being. To corroborate this assertion, a research conducted by Kim and Lee (2018) analyzed data from 28 countries and identified that the perception of inequality of opportunity is a potential moderator of attitudes toward redistribution for people at all SES levels. There is an expectation that opportunities can be equal and thus the acquisition of resources would be based on individual efforts in a fair competition.

In this way, individuals with higher SES can interpret redistribution policies as a way to benefit subjects using parasitic strategies, while lower SES are less prone to this interpretation precisely because they have less access to resources. It is only in a scenario where it is explicit that the conditions of opportunity are unequal that subjects of higher SES could support policies of redistribution.

Still, other factors must be considered. A study conducted by Sznycer et al. (2017) mapped the motivations that shape attitudes toward redistribution. For this, they started from the premise that modern redistribution is perceived as an ancestral scene involving three actors: the other in need, the other in a better situation, and the actor himself. This scene would be the central aspect in the individual understanding of redistribution in modernity. The motivation to accept redistribution would then be shaped by a mixture of humanitarian and resentful motives foreseen by this ancestral game model. The motivations that predicted support for redistribution were compassion, envy, and self-interest. Although justice is central to many of the arguments for redistribution, it has had little or no effect on support for

it. Thus, individuals with higher SES faced with this ancestral scene would be led more by the motivations of envy and self-interest rather than compassion or justice. Another motivational aspect that can help explain why people with higher SES tend to be against redistribution is social dominance. From this perspective, individuals would have evolved to achieve and maintain social dominance over other groups (Sidanius and Kurzban 2013). In order to favor group superiority, it is necessary to accumulate resources and resist redistribution.

Conclusion

In general, individuals with higher SES tend to oppose measures of economic redistribution. This is due to a series of cognitive and motivational mechanisms shaped by evolution to solve problems related to the distribution of resources in forage societies. In modern times, these systems end up reflecting individual attitudes about redistribution (e.g., anger, compassion, self-interest). In addition, status, by creating a stable system to distribute scarce resources without constant conflict, is considered to be adaptive. At the individual level, it guarantees access to resources; and at the group level, while creating inequalities, hierarchy provides stability for cooperative relations without open, constant, and widespread competition among group members. Therefore, individuals in a privileged position tend to wish for the permanence of the distribution of resources and oppose redistribution policies. For, in evolutionary terms, it is advantageous for individuals of higher SES to maintain the social hierarchy, both at the individual and group level.

Definition

In acts of high-cost altruistic helping, substantial risks to the own well-being or considerable losses of social and/or economic capital are voluntarily incurred in order to benefit others.

Introduction

Thomas H. McCann was one of the first recipients of the Carnegie Medal for civil heroism. On June 29, 1904, McCann jumped from a bridge 25 ft high into Portland Harbor and dragged Alfonso Sekosky, an 8-year-old boy, to safety on a boat, but was too fatigued to get into it himself and was drowned. McCann's case is quite representative: since its inception in 1904, the Carnegie Medal has been awarded to almost 10,000 "individuals in the US and Canada who risked their lives to an extraordinary degree saving or attempting to save the lives of others" (carnegiehero.org, September 2016). About 20% of the recipients of the Carnegie Medal did not survive their attempts to help others (Becker and Eagly 2004).

Why is it that ordinary people like McCann, who was only 32 years old at the time of his death, voluntarily take such tremendous risks to their own well-being in order to help others? Or, asking from the biological perspective, how can such prosocial behavioral inclinations be conserved or even be promoted by evolutionary forces, if they substantially increase the chance that their bearers eliminate themselves from the human lineage?

This entry reviews potential answers to these questions in light of the available empirical evidence. After a brief clarification of terms, the first main section focuses on theories that can explain the preservation and propagation of prosocial behavioral traits that cause high costs to their bearers. The second section discusses the problems that research on high-cost helping faces, before the third and fourth sections review the evidence available from controlled experimental studies and the analysis of documented historical cases of high-stakes prosocial behavior in the domains of civil life and warfare. The concluding

section points out important open questions and suggests directions for future research.

Disambiguations

Dying in the course of his heroic action, Thomas H. McCann paid a high price, his own life, for the protection of a boy who, presumably, was a total stranger to him. But what if he had died rescuing one of his sons instead? Would we think of his action as equally honorable? If we take the eligibility criteria of the Carnegie Medal as a proxy for prevalent societal norms about which kinds of actions are considered heroic, then the answer is “yes”: “Persons not eligible for awards are: [...] members of the immediate family, except in cases of outstanding heroism where the rescuer loses his or her life or is severely injured” (carnegiehero.org). Still, callous Darwinian evolutionary logic states that the price paid by McCann is higher, *ceteris paribus*, than the one a father pays when dying for the life of his offspring. Obviously, thus, the Darwinian costs of high-stakes prosocial behavior can differ. Therefore, before we review potential explanations for how such behaviors might evolve, let us briefly recapitulate the underlying evolutionary calculus.

The currency of natural selection is fitness, which can be approximated as the expected number of copies of a given gene that an individual is able to successfully pass to the next generation. Therefore, when analyzing the prospects of evolutionary success of a certain behavioral trait coded for by one or multiple genes, we need to take into account that trait’s *direct* fitness consequences on its bearer, as well as its *indirect* fitness consequences on individuals bearing the same gene or genes. Furthermore, it is important to note that the fitness balance, F , of a certain trait can only be evaluated after aggregation over the *entire lifetimes* of all individuals affected by the behavior, because both direct and indirect fitness consequences, D and I , respectively, can each have an immediate and a delayed component. For short, let us define the fitness balance of a trait as: $F = D_{\text{now}} + I_{\text{now}} + D_{\text{later}} + I_{\text{later}}$. As we will see, all of these components can play crucial

roles in explanations of the evolution of high-cost prosocial behaviors and altruism, which, in terms of direct and indirect fitness consequences, can now be defined as follows.

According to West et al., four types of behavioral traits need to be carefully distinguished, based on their *direct* fitness consequences (i.e., $D_{\text{now}} + D_{\text{later}}$) for the acting individual: *mutualistic* “+/+” behaviors benefit all affected parties, *spiteful* “-/-” behaviors cause costs for all parties, *selfish* “+/-” behaviors benefit the acting individual at a cost to those affected, and *altruistic* “-/+” behaviors benefit those affected at a cost to the actor (West et al. 2007). While natural selection can potentially favor mutualistic and selfish behaviors straightforwardly, because of their positive effects on direct fitness, spiteful and altruistic behaviors can evolve only if their negative effects on direct fitness are offset by sufficiently high indirect fitness benefits, i.e., if their *inclusive fitness* balance is positive.

One important point to note about this definition of altruism is that not only the immediate direct fitness consequences of a behavior need to represent a cost to the acting individual but that their overall direct fitness effects need to be negative, i.e., $D_{\text{now}} + D_{\text{later}} < 0$. Thus, if the immediate direct costs of behaving to the benefit of others are offset by direct benefits accrued later, such behavior does not fall under the category of altruism *sensu* West et al. but represents mutualistic behavior instead. To avoid terminological confusion, thus, we will refer to any kind of action to the benefit of others as “helping” and only speak of altruism if $D_{\text{now}} + D_{\text{later}} < 0$ actually holds for a specific action.

A second important point to note is that the effective costs of a certain type of prosocial behavior can differ between individuals. Obviously, the risk of drowning while swimming to the rescue of a person in distress is much lower for an experienced and athletic swimmer than for someone who swims only infrequently. That means: for the latter $D_{\text{now}} < 0$ likely holds, while the experienced swimmer is more likely to face a $D_{\text{now}} \approx 0$ type of risk. The classification of an action as “costly,” thus, requires a thorough prior evaluation of the fitness effects an action

potentially has on the respective acting individual. As will be discussed later, this second point mainly is a problem for empirical studies on helping behavior. The theories reviewed in the following section, however, can all explain how helping might evolve also when it is effectively costly, i.e., when $D_{now} < 0$.

Theory: How Can Helping Evolve, Particularly if It Is Extremely Costly?

Numerous theories exist that can explain how behavioral traits causing immediate direct fitness losses to their bearers might eventually be preserved and even favored by natural selection (see, e.g., Kurzban et al. 2015; Nowak 2012, for overviews). Using the terminology just introduced, their common rationale can be summarized as follows. In order for such a trait not to go extinct in the long run, its inclusive fitness balance, F , must be zero or positive. If one or more of the terms of this sum are negative, thus, at least one of the other terms must be positive and large enough to compensate for the negative terms.

All theories on the evolution of costly helping behavior start from the assumption that $D_{now} < 0$. They differ in their assumptions about which other components of the inclusive fitness balance are eventually compensating for these costs (see Table 1). The first set of theories – *costly signaling*, *direct reciprocity*, and *indirect reciprocity* – all identify delayed direct fitness benefits to the helper, D_{later} , as the compensating factor. Costly helping of this kind, thus, does not represent altruism sensu West et al. (2007). Let us briefly review these theories in turn.

Costly signaling. The main idea behind the theory of costly signaling is that individuals differ

in characteristics that determine their attractiveness to others as social and/or sexual partners but that are not directly or reliably observable (Spence 1973; Zahavi 1975). By engaging in costly helping, those individuals who can afford the respective costs, e.g., because they are physically fit or wealthy enough to do so, can reliably signal two characteristics that increase their attractiveness: their physical or economic capabilities and their prosociality. Such unforgeable public displays, in turn, increase the chances for the signalers to benefit from social interaction with choosy high-quality partners later on, by whom they might otherwise have been ignored (for further discussion, see, e.g., Barclay 2011).

Direct and indirect reciprocity. While the recipients of help eventually play no role other than causing a cost to the signaler in costly signaling theory, they are more important for the theories of direct and indirect reciprocity (Nowak and Sigmund 2005; Trivers 1971). Direct reciprocity theory assumes that the initial cost of helping is eventually overcompensated by the returns from a longer-term cooperative partnership between the helper and the recipients of help that results from this initial act of benevolence. Indirect reciprocity theory, on the other hand, assumes that helper and recipient might never meet again. Instead, the cost of helping here is compensated indirectly through help that the helper herself receives from third parties later on who base their decisions to help on reputation. In order to maintain a good reputation, and thus to receive help if needed, one must help others if they are in need. Hence, under regimes of indirect reciprocity, costly helping buys helpers access to a community of cooperative social partners and

eventually makes them better off than living in a community of non-helpers (for further discussion, see, e.g., Roberts 2008).

As we have just seen, the three previous theories assume delayed, but positive, direct benefits to the helper, i.e., $D_{later} > 0$. One might be tempted to interpret this assumption as meaning that these theories only work in case helpers always survive, because otherwise they cannot benefit from these delayed direct fitness benefits. This is not the case, though. All that $D_{later} > 0$ requires is that there is a positive chance of surviving for the helper, because what counts from the evolutionary perspective is not the fate of any single individual, but rather the “average fate” of all bearers of a specific trait over a longer period of time, of course. Still, there are at least two theories that can potentially also explain the evolution of traits that lead to their bearers’ death with certainty, i.e., theories that work even if $D_{later} < 0$.

Inclusive reciprocity. The first of these theories, inclusive reciprocity, is an extension of the theory of indirect reciprocity (Albert and Rusch 2013). Its central idea is that reputation is not necessarily limited to individuals, but can span entire groups or families of individuals. If parental reputations are inherited by the offspring, e.g., altruistic behavioral traits can evolve that cause a parent’s death, if they lead to a sufficiently high increase of the offspring’s reputation, i.e., if they make I_{later} sufficiently large. Note that under inclusive reciprocity, altruistic traits can evolve even if they do not benefit the offspring directly in any way and even if they cause immediate costs to them, because inclusive reciprocity works through delayed indirect benefits.

Kin selection. The other theory that is potentially able to explain the evolution of “lethal helping” is kin selection, i.e., inclusive fitness theory. Just like inclusive reciprocity, kin selection theory assumes that direct fitness costs to the helper are eventually compensated by indirect benefits, i.e., benefits to the helper’s kin. The main difference between the two theories is that inclusive fitness theory assumes that the act of helping itself causes these indirect benefits, while inclusive reciprocity assumes that they are mediated by the reputational gains that the act of helping causes for the

offspring of the helper, i.e., by “family reputation.” Inclusive reciprocity, thus, requires that individuals are able to track reputations and to condition their behavior on them, while inclusive fitness theory is less demanding. Kin selection only requires that altruistic acts have positive indirect effects on helpers’ kin in the long run. Note that this does not even require that individuals are able to discriminate between kin and non-kin. All that is needed is a clustering of kin groups in a given population such that the average expected fitness consequences of helping are higher for relatives of the helper than for non-kin (Kümmerli et al. 2009).

Mismatch. Before we move on to discuss how the explanatory value of the theories just outlined could be tested on the background of the available evidence on acts of high-cost helping behavior, one important possibility must not go unnoticed. As is known, natural selection usually works slowly. Given that, from an evolutionary perspective, the time during which humans lived in small bands of quite closely related mobile hunter-gatherers is “just” over, contemporary high-cost altruistic helping, i.e., helping with $D_{now} + D_{later} < 0$, may have become dysfunctional through the rapid changes in human social organization over the last 15k years. Therefore, while such prosocial behavior may have had significant positive effects on kin in ancestral times, the “mismatch hypothesis” states that these effects are no longer present today and that evolution might simply not have caught up with this fact.

The Intricacies of Studying High-Cost Helping

It is not hard to see that testing the aforementioned theories against each other is not a straightforward task. While the mismatch hypothesis makes for a suitable null hypothesis, and may thus receive some support in case all alternative theories should fail, researchers trying to find supportive evidence for these alternative theories face numerous problems.

One intricacy on the theoretical side is, for example, that many of the suggested explanations for the evolution of high-cost helping are not mutually exclusive. As can be seen from Table 1, evidence of delayed direct benefits, $D_{later} > 0$, for

instance, can yield support for costly signaling as well as for direct and indirect reciprocity. Disentangling further which, if any, of these three theories receives more support if evidence for $D_{later} > 0$ is actually found, thus, requires refined research designs and/or more fine-grained data gathering efforts.

On the empirical side, on the other hand, researchers of high-cost helping behavior face even more taxing challenges. For obvious reasons they cannot put experimental subjects into life-threatening situations or confront them with decision situations involving other types of high personal costs. To work around this problem, at least three approaches to approximating such situations under controlled conditions have been used in the literature. Naturally, they all have their respective up- and downsides.

The first commonly used approach is to focus on the question of how – real or fictitious – persons who engaged in high-cost helping are perceived by third parties. Using this approach, researchers can experimentally manipulate certain characteristics of the helper, the recipients of help, the situational context, etc. The second approach is to ask subjects how they would behave in hypothetical scenarios requiring high-cost helping – the characteristics of which can again be experimentally manipulated, including the priming of subjects with mind-sets of interest, like mating motives or high group coherence. Of course, both these approaches face the common problem that the data they yield stem from self-reports and are not readily generalizable to the real-world analogs of the persons and situations studied in the laboratory. They are, however, able to establish causal relations, which makes them an indispensable tool in the study of high-cost helping.

Apart from using self-reports, researchers have also used economic decision-making experiments to study high-cost helping. In these, subjects are endowed with money and asked to decide if they would like to use their endowment to help one or multiple persons in need. In addition to being able to reveal causal relations as well, the second benefit of studies of this kind is that subjects make decisions that have real monetary consequences for themselves and other persons. Through

increasing the size of the endowment, these studies can then approximate situations of helping at high personal costs. Apart from the practical challenge that such studies can become arbitrarily expensive, they face at least three additional problems. The first is that endowments usually are “windfall” money to the subjects, i.e., free money that they might spend more laxly than money they earned outside the laboratory. The second problem is that the same amount of money may be of quite different value for different subjects. Comparisons of economic decisions between individuals, or even countries and cultures, therefore, should ideally simultaneously control for individual- and group-level differences in wealth and in the endowments’ purchasing power. The third problem, finally, is fittingly captured in the commonplace that “money can’t buy everything,” meaning that even decisions involving very high monetary stakes may psychologically not have the same gravity as fitness relevant decision situations involving immediate threats to one’s survival and/or reproductive prospects.

Complementary to studying high-cost helping experimentally under controlled conditions, a second main branch of the literature has developed that analyzes data on documented historical cases of such behavior (also see Rusch 2016). Just like all other studies that are based on historical data, this branch of the literature faces all the problems caused by the impossibility to control the conditions from which these data originate, of course. These problems include, but are not limited to, sampling bias, undetected confounding factors, data availability, and measurement problems.

Sampling bias, for instance, represents a potential obstacle for researchers who gather case data from sources like the Carnegie Hero Fund. Naturally, those cases of civil heroism available from this source were selected for being publicly honored by the fund’s selection committee. The underlying process of nomination, screening, and eventual selection or rejection by this committee might, of course, be influenced by shifts in societal norms, changes in the composition of the committee, adjustments of the eligibility criteria or new views on how they are to be interpreted, etc.

Apart from potentially biasing selection committees' work, societal norms can also represent confounding factors that may affect research using historical data, of course. The fact, e.g., that – to date – there is only one woman among the roughly 3,500 recipients of the highest US military award, the Medal of Honor, must not be taken to indicate that women are very unlikely to behave bravely in combat. Obviously, instead, women simply did not have the opportunity to display such bravery until the fourth quarter of the twentieth century during which they were gradually admitted to all branches of the US military. Other important potential confounders include contraceptives, which interfere with the study of reproductive success after the 1950s, or socioeconomic status and urbanization which may reduce the exposure of individuals to certain types of life-threatening situations.

In addition to being subject to these aforementioned complications, finally, research on historical cases of high-cost helping virtually always suffers from limited data availability. Trying to track the reproductive success of specific individuals, e.g., is a time-consuming endeavor and usually results in incomplete data. A standard problem in this process is the identification of extramarital offspring, which is usually impossible. Furthermore, the available information on specific individuals, even if accessible, often is limited, thus forcing researchers to either base their analyses on sub-optimal proxy variables or even to leave interesting questions unanswered.

In summary, research on high-cost helping faces both theoretical and, maybe more importantly, numerous practical problems. Still, as the following sections will show, a number of instructive empirical studies on this type of behavior exist. They are listed in Table 2. Although each of these studies faces specific limitations, some of which were just outlined, a number of more general insights already become apparent from the overall picture drawn by the available evidence. Therefore, instead of describing each study individually, the following two sections try to summarize these more general insights.

Evidence from Controlled Experimental Studies on Helping Behavior

The standard paradigm for studying costly helping behavior in economic experiments is the dictator game. In this game, subjects are randomly matched into pairs. One subject is then assigned the role of the dictator and the other the role of the recipient. The dictator receives an endowment from the experimenter and can decide how much of it she would like to share with the recipient. The recipient, on the other hand, does not make any decisions. Experimental designs usually ensure that dictators can make their decision in private and that dictator and recipient do not know each other, cannot communicate, and are very unlikely to meet after the experiment. Generally, thus, the aim of dictator game designs is to make sure that dictators do not have to fear any negative consequences, but also cannot expect any positive ones, irrespective of what they decide. Still, across studies (Engel 2011) and across cultures (Henrich et al. 2001), remarkable proportions of dictators decide to share a part of their endowments with the recipient, 28% on average (Engel 2011). As discussed above, however, these endowments are usually comparably small.

Stakes effects in dictator games. What happens, now, when endowments are increased? Two recent meta-studies tried to tackle this question (Engel 2011; Karagözoğlu and Urhan 2016) and arrived at mixed conclusions. Analyzing data on average giving rates in 158 experimental conditions from studies in which endowment sizes were systematically varied, Engel (2011) finds that increasing endowment size seems to have a small negative effect on dictators' willingness to share. However, for his larger sample of 440 conditions from dictator games for which dollar equivalents could be computed, Engel finds no such effect, with stakes ranging from \$0 to \$130. Karagözoğlu and Urhan (2016) arrive at similarly mixed conclusions. Intriguingly, a recent study on the giving behavior of dollar millionaires, furthermore, found millionaires playing with an endowment of €100 to make the most generous dictator game decisions observed in the literature so far (Smeets et al. 2015).

With respect to high-cost helping, thus, the existing literature on dictator games suggests two things. For one, the readiness to share wind-fall money with others may be relatively insensitive to stake size. From a methodological perspective, this could be regarded as good news, as it yields some support for the assumption that costly helping behavior can be studied in the lab using comparably small stakes without losing too much generalizability. Importantly, however, the range of stakes used in the existing dictator game literature is still limited to three-digit dollar amounts. We currently do not know what happens if stakes are increased beyond this (for further discussion, see Karagözoğlu and Urhan 2016). For the other, as the millionaire study by Smeets et al. (2015) indicates, it is important to keep in mind that the same monetary stakes may be of very different value for different subjects. Revealingly, when asked by Smeets et al. to explain their decisions, many of the millionaires gave answers like “With my money, 100 euro is easy to give” (see the supplements to Smeets et al. 2015).

Rating studies. A somewhat clearer picture emerges with respect to the results of studies that asked participants to rate fictitious persons who engaged in high-cost helping. Focusing

predominantly on high-cost helping as an honest signal of desirable qualities as a mate, the existing studies consistently find positive effects of helping on ratings of attractiveness. In addition, Griskevicius et al. (2007) report that subjects who were experimentally manipulated into a mating mind-set self-reported a higher readiness to engage in certain types of costly helping behavior toward third parties. Thus, convergent evidence exists in the literature that costly helping does increase perceived attractiveness and that it may also be used, intentionally or unintentionally, as a means to display personal qualities on the mating market. The literature is less univocal, however, with respect to the question if using costly helping as an honest signal is a sex-specific phenomenon or not. While Griskevicius et al. (2007) report that their experimental manipulations yield stronger effects in men, many other studies find that both men and women positively react to displays of costly helping by rating helpers as more attractive than both non-helpers and neutral persons with otherwise identical characteristics. Furthermore, the literature also is inconclusive with respect to whether helpers are preferred as long-term or short-term partners or both. Unfortunately, because of the focus of most studies on costly

helping as an honest signal in the context of mating, the literature also does not offer a decisive answer with respect to the question of whether there are additional benefits to costly helping through indirect reciprocity. At least, Kelly and Dunbar (2001) report that helpers are also rated as more preferable social partners, i.e., friends, by women.

In summary, the literature on costly helping as a “courtship display” (Barclay 2010) provides quite consistent evidence that various types of costly helping behavior actually seem to increase perceived mate value. However, the questions of whether this effect is sex-specific and whether costly helping is also an effective signal in other contexts than mating are not answered conclusively by the existing studies.

Evidence from Documented Historical Cases of High-Cost Helping

Given these results from controlled laboratory studies, the logical follow-up question of course becomes, if they can help us understand the occurrence of real-world high-cost helping behavior better. To date, however, only comparably few studies have tried to shed light on this question, each of them focusing on rather distinct aspects of this kind of behavior. Their data, furthermore, mainly stem from two sources only: the Carnegie Hero Fund and the official Medal of Honor citations (also see Rusch 2016).

Civil heroism. Recipients of the Carnegie Medal, “civil heroes” for short, have been analyzed in five studies so far (see Table 2). Their main common observation is that the Carnegie Medal is predominantly awarded to men (roughly 90% of all recipients, see Becker and Eagly 2004). Notably, the only study using an alternative data source, UK newspaper articles on cases of civil heroism (Lyons 2005), confirmed independently that civil heroism is more likely to be displayed by men. Two other observations were also made repeatedly. First, civil heroes likely have an increased probability of belonging to the working classes (Johnson 1996; Lyons 2005). Second, civil heroism seems to occur more often in rural regions as compared to urban ones (Johnson 1996; Lay et al. 1974).

It is tempting to take these three repeatedly made observations as evidence supporting two of the theories outlined above. The overrepresentation of men among civil heroes suggests that this type of high-cost helping might be a sex-specific costly signal. The tendency of civil heroes to have low socioeconomic status and the more frequent occurrence of civil heroism in rural areas might indicate that indirect reciprocity is playing an important role, as anonymity is likely to be lower and a good standing in one’s community likely to be more important in rural areas and in social strata in which mutual favors cannot be substituted through buying the same services.

However, with respect to sex bias, Becker and Eagly (2004) argue that the overrepresentation of men among civil heroes might be due to the physically challenging nature of those specific types of acts of helping conventionally subsumed in the category of “civil heroism.” In fact, Becker and Eagly are able to show that for other types of brave and potentially very costly actions, such as hiding Jews from the Nazis or donating a kidney, among others, no such bias exists – and even that women are overrepresented among some of these other groups of helpers. For the findings on social status and region, on the other hand, Lay et al. (1974) and Johnson (1996) point out that similar caution needs to be applied. It could be that those types of situations allowing for actions of the types most frequently honored as civil heroism are just more likely to occur in rural regions and in contexts that members of the lower social strata are more frequently exposed to.

War heroism. The actions of the recipients of the Medal of Honor, “war heroes” for short, represent the second source of historical case data on high-cost helping behavior frequently used in the literature. Seven studies exist that have studied selected characteristics of these men and the contexts of their heroic actions. However, the only finding that has been repeatedly reported across studies concerns cases of “heroic suicide,” i.e., the deliberate sacrifice of the own life by covering an explosive device in order to save the lives of fellow soldiers in close proximity. Analyzing

partially overlapping data extracted from the official Medal of Honor citations from different wars, Blake (1978), Riemer (1998), and Rusch and Störmer (2015) all report that this kind of high-cost helping behavior is observed more frequently in lower-ranking soldiers and in members of the Marine Corps. Other noteworthy, but singular, findings reported in this literature include that surviving Medal of Honor recipients of WWII seem to have had increased reproductive success compared to other veterans of this war (Rusch et al. 2015) and that acts involving direct help to comrades are more frequently observed during defenses (Rusch 2013).

The finding of increased reproductive success of WWII Medal of Honor recipients apparently yields direct support to the idea that war heroism might be a costly signal favored by sexual selection. However, in addition to pending replication using data from other times, regions, and sources, numerous confounding factors could not be ruled out by Rusch et al. (2015), and their finding therefore needs to be interpreted with due caution. To name just one limitation, they could not rule out, for instance, that the material benefits associated with the Medal of Honor might have allowed its recipients to support a bigger family as compared to regular veterans.

With respect to the observation that enlisted men and members of elite troops seem more ready to “make the ultimate sacrifice,” the same caveat applies as with apparent status and provenance effects in civil heroes. It could simply be that enlisted men and elite troops are more frequently exposed to situations in which such a sacrifice can be made. However, data that allow controlling for this potential confounding factor currently are unavailable and, unfortunately, are likely to remain so as gathering them seems hardly feasible.

Conclusion

This entry has reviewed selected evolutionary theories that can potentially explain how behavioral traits causing their bearers to lend help to others can be sustained and also promoted by

natural selection even when the acts of helping cause high costs for the helpers. Subsequently, the intricacies of testing these theories against the results of laboratory and archival data studies were discussed. Finally, the existing empirical literature on high-cost helping was summarized briefly.

Contrasting the broad spectrum of suggested theories to the sparseness of available empirical work on high-cost helping, it becomes immediately apparent that intensified research is needed. The only theoretical suggestion, for which more than a modicum of empirical support has been found so far, is costly signaling. Costly helping does indeed seem to increase the perceived attractiveness of helpers as mates and may even have resulted in increased reproductive success in some historical cases. This should not be taken to mean, though, that the other theoretical suggestions – direct, indirect, and inclusive reciprocity and kin selection – have received no support so far. They simply have not been tested in the study of high-cost helping, yet.

Given the continuously increasing availability of data sources on historical cases of high-cost helping from online databases and the steadily improving accessibility of biographical information on historical persons, significant progress in this area of research can be expected in the nearer future, though. Particularly, since instructive recent studies have already pioneered ways of accessing and analyzing such sources (Lyons 2005; Rusch et al. 2015).

Apart from the imperative need to replicate earlier findings using alternative data sources and better controls to rule out potentially confounding factors, important research questions to be tackled include the following: To which extent is costly signaling in the form of helping a sex-specific phenomenon? Apart from increased mate value, which direct and indirect benefits, if any, do high-cost helpers regularly obtain, and what are their effects on helpers’ fitness balances? And finally, do the available theoretical suggestions suffice to explain the occurrence of the dark flip side of “lethal helping” in the form of suicide attacks (Atran 2003)?

Definition

Social status refers to differential degrees of social influence and rank in relation to other group members. This definition is used in the current entry. Note, however, that variations in definition exist across disciplines (and sometimes subfields): in some areas of research, for instance, social status is used to describe freely conferred deference or prestige, in contrast to the use of the term here to refer to more general influence that may or may not be associated with respect or prestige.

Introduction

From the most egalitarian societies to the formal organization of contemporary businesses, human groups are inherently structured by social hierarchy (Eibl-Eibesfeldt 2017; Mazur 1985; Von Rueden 2014). That is, differentiation in social rank – defined as relative position within a social hierarchy based on social influence and agency (Báles et al. 1951; Berger et al. 1980) – is persistently observed within and between groups. The

ubiquity of social hierarchy and rank differentiation likely emerged because hierarchies ease the tensions between competing group members who may have conflicting goals, and thus facilitates effective collective action and reduces the frequency of agonistic conflicts (Anderson and Willer 2014). Such rank differentiation is characterized by two dimensions: power and social status (see Blader and Chen 2014 for a review).

Power generally refers to institutionally legitimized and endorsed influence that is characterized by an individual’s ability to influence others through fear and harnessing control over resources (Keltner et al. 2003). Social status, on the other hand, refers to informal rank and influence that can be achieved by those who lack formal power or institutional roles. Power and social status have distinct antecedents and divergent consequences for both individuals and groups (Hays and Bendersky 2015). The current entry will, however, focus solely on the antecedents and consequences of having higher social status in human groups.

Social status in human groups can either be freely conferred to respected and admired individuals by other group members or coercively imposed on group members by a forceful, aggressive and manipulative individual. These two often distinct forms of social status are underpinned by individual differences in prestige and dominance within a group (Cheng et al. 2010). Moreover, social status (also termed *sociometric status*) is conceptualized differently to *socioeconomic status*, which is characterized by an individual’s occupational status, educational attainment, and income (Adler et al. 1994).

The Antecedents of Higher Social Status

Freely Conferred Status

Freely conferred social status is allocated to individuals by others within their group. Unlike power and coercively imposed status, freely conferred status is highly dependent on the collective perceptions of group members about an

individual's instrumental value in a respected cultural domain (Henrich and Gil-White 2001; Leary et al. 2014). There is often consensus among group members in judgments of an individual's social status (Mast and Hall 2004) and those high in social status are often conferred considerable influence over group decision-making (Cheng et al. 2013). As freely conferred status is granted by others, it is an inherently relational process. More specifically, an individual can only be high in status when those around them exhibit deference, and thus social status is not a characteristic of the individual but the property of a dyad or group (Bunderson et al. 2016; Emerson 1962).

Individuals often confer social status to those who they perceive to have an ability to confer benefits to group members. Those who provide skills (i.e., making effective arrowheads), expertise (i.e., botanical knowledge for medicinal practices), and exhibit traits that signpost physical ability (i.e., physical strength and size) are often granted higher social status in their groups (Anderson and Kilduff 2009a; Von Rueden et al. 2008). These abilities and expertise are often associated with narrower personality traits and individual differences – such as extraversion, conscientiousness, and openness – that may motivate the accrual of such skills. Prestige is also associated with agreeableness and genuine self-esteem, which may also help individuals prosocially monitor and maintain their social standing within groups (Cheng et al. 2010). All of the aforementioned traits and abilities are important for a group's success and survival (Ellis 1994), help to establish hierarchical relationships based on respect and admiration, and comprise a *prestige* profile (Henrich and Gil-White 2001). This prestige profile is associated with social or cultural learning, whereby the traits that signpost prestige highlight an individual's propensity as a teacher (or so-called learning model) to observers (so-called *info-copiers*), who in turn aim to maintain proximity and seek advice from that individual (Henrich and Gil-White 2001). Through this learning process, the individual high in prestige may confer adaptive skill or knowledge to the info-copier – such as how to produce a usable arrowhead – and thus

facilitate that individual's own goal accomplishment (Barkow 1975).

Acquiring social status through prestige is not only reliant on an individual's ability, but also their willingness, to bestow benefits to others. Experimental evidence suggests that those who contribute most generously achieve the highest levels of social status within a group (Barclay 2013; Willer 2009). These acts of generosity and cooperation may effectively broadcast an honest signal of an individual's prestige (see Bliege Bird and Smith 2005). More specifically, by signaling generosity and cooperative intent, high prestige individuals relinquish valued resources – be they informational or material – that will benefit other group members and further signal their quality within their group. In return, the individuals receiving the signal freely confer deference to their high-prestige counterpart and further elevate that individual's social status within the group (Boone 1998; Gintis et al. 2001; Roberts 1998). Indeed, a large and growing body of empirical evidence suggests that the most capable individuals who are willing to provide benefits are allocated the highest social status across many small-scale societies (Sugiyama and Sugiyama 2003; Wiessner 2005), among North American task groups (Cheng et al. 2013; Lukaszewski et al. 2016), and also during development (Hawley 2002; Redhead 2016).

Coercively Imposed Status

In some circumstances, individuals may achieve social status through coercion and cost imposition. Individuals acquire such coercively imposed status through dominance, which is related to an individual's ability and willingness to inflict costs on others (see ► “[Individuals That Impose Costs](#)” by Redhead et al., this volume for a detailed overview). Unlike freely conferred status, coercively imposed status is not the property of the group. More specifically, it is not granted through a process whereby group members collectively agree upon an individual's social value to the group. Rather, individuals defer to their high dominance counterparts in an attempt to lessen the costs that the individual high in dominance may impose on them, even if they may not necessarily

wish to. Thus, such coercively imposed status is underpinned by fear (Cheng et al. 2010, 2013). Without such fear, an individual's coercively imposed status would diminish. In many contexts, there are a several mechanisms characteristic of human groups that lessen the efficacy of dominance, such as the ability of group members to form coalitions (Boehm 2009; see ► [“Individuals That Impose Costs”](#) by Redhead et al., this volume).

Often dominance is related to power. Those who have disproportionate control over a group's resources and are willing employ coercive tactics to attain their egocentric goals are more able to leverage such control and successfully spread fear among proximate others (Mazur 1985; Wrangham 1980). In addition, there is variability in the efficacy of dominance's association with social status (Anderson and Kilduff 2009b). In most social groups, dominance typically has no substantial relationship, or a negative relationship, with prestige (Cheng et al. 2010; Redhead 2016). However, in some contexts, dominance and prestige may be positively related. For example, in groups and cultures whereby an ability to inflict harm is respected (i.e., during development, in delinquent gangs, prison populations), dominance may have a positive association with both prestige and higher social status in groups (Hawley 1999; see ► [“Status Competition and Peer Relationships in Childhood”](#) by Redhead et al., this volume). More broadly, individuals may at times both respect and fear their superiors (Barkow 2014). This relationship has received scarce empirical investigation and provides a fruitful platform for future investigation.

The Consequences of Higher Social Status

There are abounding benefits of having higher status in groups. First, evidence from various societies indicates that those high in both freely conferred and coercively imposed status have greater access to sexual resources (Alden Smith 2004; von Rueden and Jaeggi 2016) and have lower offspring mortality (von Rueden et al. 2010). Those high in

freely conferred status are attractive as long-term sexual partners, while those high in coercively imposed status are more attractive short-term partners (Kruger and Fitzgerald 2011). Complimentary to this, individuals perceived as contributing more to the goals of a group – and thus attaining positions of higher social status – are perceived as more physically attractive by their lower-status counterparts (Kniffin and Wilson 2004), and individuals perceive the leaders of their in-group as more physically attractive in comparison to leaders of an outgroup (Kniffin et al. 2014). Alongside these, high status individuals tend to have higher numbers of allies and cooperative partners (Patton 2005; Von Rueden et al. 2008), and have privileged access to a group's valued or scarce resources (Ellis 1994). It seems that having high social status increases an individual's overall fitness (Wiessner 2005) and may be considered a fundamental human motive (Anderson et al. 2015; Barkow 1989).

Having high social status also has a positive impact on the health and subjective well-being of individuals. Among the Tsimane forager-horticulturalist of Bolivia, individuals higher in status had greater nutritional health (Reyes-Garcia et al. 2008). Across cultures, individuals who feel more respected are higher in life satisfaction and positive affect (Tay and Diener 2011). Evidence also suggests that, during adolescence, individuals low in prestige are more likely to be bullied (Sijtsema et al. 2009) and adolescent girls who are perceived as leaders are also perceived as being happier (Weisfeld et al. 1984). Moreover, individuals high in freely conferred status are less likely to exhibit poor mental (i.e., depression: (Cooper et al. 2010) and physiological health (Ghaed and Gallo 2007) than their lower status counterparts. There are, however, several negative consequences of coercively imposed status (see ► [“Individuals That Impose Costs”](#) by Redhead et al., this volume).

Conclusion

Differentiation in social status seems universal for human groups. Individuals are granted positions

of high social status by members of their groups through prestige, a profile grounded by an individual's ability and willingness to confer benefits to others, and dominance, which is centered on the ability and willingness to inflict harm on others. Overall, there are many benefits related to high social status in groups.

Higher Survival with Older Siblings

Definition

Examination of cultural provisions of childcare suggests that the presence of female alloparents including maternal relatives, friends, and older siblings result in higher survival rates.

Introduction

In comparison to animals, newly born human babies are entirely dependent on their caregivers and need sensitive care and attention to survive. In most cultures, the necessary care and attention are provided by mothers and perhaps that is why, when a mother dies, the probability of infant surviving becomes slim, unless the caregiver is replaced by another sensitive human being (Brittain 1992). The positive correlation between maternal and infant mortality is quite evident in Scandinavian countries with the lowest maternal and infant mortality rates and African countries with the highest maternal and infant mortality rates (World Bank 2018). Citizens of countries with very high maternal and infant mortality rates face the biggest challenge of first surviving their childhood and becoming reproductively successful adults, and then raising their children to adulthood (Volk and Atkinson 2008).

Since, raising a human infant requires immense levels of sensitivity, investment, and care during the child's early years, in case of the death or disability of the mother, caregiving needs to be delegated to multiple caregivers. Ideally, kin caregivers a.k.a. alloparents are considered to be the best choice. Alloparents refer to individuals other than biological parents who assist in childcare or reciprocate childcare. Although most alloparents are chosen from the kin, but may also extend beyond kin as in case of foster children. The role of alloparents in many cultures is extensive and multifaceted. Hewlett (1991) found that among many foraging societies, for the 20–50% of the time an infant is held, it is by someone other than the mother, and most often a close female relative or trusted babysitter. Among the Efe, allomothers on occasions will nurse another woman's child if the mother is not

available (Hewlett 1989). Sear and Mace (2008) examined 45 studies of kin-child rearing patterns among people living in nonindustrialized groups and found that after mothers, maternal grandmothers have the most significant effect on increased child survival (see entry ► [“Mothers and Maternal Grandmothers and Childhood Survival”](#)).

Hence, in most cultures, especially with high maternal mortality rates, raising a child is not the sole responsibility of the parents, but is often executed by other female kin members such as grandmothers, aunts, and sisters as part of kin keeping. Many researchers have shown that kin keeping or investment by extended family members in raising children can be a function of gender, perceptions of genetic relatedness, and discriminative care (DeKay 1995; Laham et al. 2005). Subsequently, it is no surprise that maternal grandmothers and aunts are most involved in childcare due to higher perceptions of genetic relatedness and lower perceptions of paternity uncertainty (Bishop et al. 2009; Milardo 2009).

This brings us to the first question – in the early childhood years, does the relationship between alloparent and the child improve the child's mortality rates and developmental outcomes? Sear et al. (2002) investigated this question and reported that in the Gambia, maternal death was the most significant predictor of infant mortality rates; however, the rates were significantly lower in the presence of maternal grandmothers or older sisters. As anticipated from gendered norms of caregiving and perceptions of genetic relatedness, presence of paternal grandmothers and grandfathers, maternal grandfathers and older brothers had no significant effect on child mortality at any age. For this entry, we will focus on the impact of alloparenting by older siblings (generally sisters) and its outcomes on the survival of young children.

Alloparenting by Siblings and Cultures

In many cultures, older sisters assist their mothers, in taking care of their younger siblings (Weisner

et al. 1977), thereby curtailing net parenting costs (Sieff 1990). These contributions by older sisters may continue to prove beneficial to her younger siblings even after marriage. For example, in Hungarian rural communities, Romani girls contributed substantially in housework and childcare of younger siblings even after their marriage. As a consequence, there is a marked improvement in the longevity of mothers' reproductive careers and reduction in inter-birth intervals (Bereczkei and Dunbar 2002).

Older daughters, being relatively free of financial and more strenuous household responsibilities, are often seen as "Helpers at the nest" and mother's assistants. The term "helpers at the nest" has been borrowed from the study of birds (Emlen 1984) and was initially applied to the human species by Turke (1988). Turke (1988) found that women with older daughters had a better reproductive outcome than those who had sons, and this positive reproductive outcome was enhanced further in families who had two older daughters. To elaborate, a recent study ($N = 338,504$ for children aged 1–5) by Raj et al. (2019) in India drew analogous conclusions; infants with two older sisters had lowered infant mortality in comparison to those with an older brother.

This effect varies across cultures and may depend on the gender of the older siblings. Some researchers (Das Gupta 1987; Kemkes 2006; Muhuri and Preston 1991) found increased mortality when children have older siblings, especially an older brother. The rationale provided in these studies ranged from biased parenting in patriarchal societies to a lack of available resources. For example, preference for a male child in patriarchal societies may result in neglect of a female infant, or if the older sibling is not much older than the youngest child and competes for the same kinds of care and attention, the positive sibling effect on infant mortality can be negated or even reversed.

Now that we have established that females are generally the caretakers of young children more than twice as often as males (Weisner 1987) and improve the odds of infant survival, the second question is, what do sisters do to improve the survival rates of their younger siblings?

Sibling Caregiving

Sibling relationships are one of the longest-lasting relationships (Bank and Kahn 1982), and older siblings may have direct and indirect effects on their younger siblings. In early childhood, responsive and supportive interactions between siblings can be a source of secure attachment for the younger siblings (Ainsworth 1978). As previously noted, female children begin to contribute toward domestic chores, childcare, and the economic well-being of the family at an early age (Hames and Draper 2004). For example, in Dominica, girls as young as 12 years of age, spend a similar amount of time on domestic activities as adult women (Quinlan et al. 2003). Consequently, the mothers are relieved from the domestic burden and spend more time in taking better care of their infants and toddlers.

These tasks can depend on the priorities of the mothers in these cultures, the age of the children providing help, and the age of the children receiving it. In the Toba of Argentina, older girls' tasks depend on the age of the infant; girls focus on domestic tasks when mothers are nursing, so they do not provide childcare as much as free the mothers to provide milk and nurturance at this crucial time. Within these same homes, older girls assist a great deal more than younger girls and are more likely to care for children, and not perform simple domestic tasks (Bove et al. 2002). Overall, the tasks are scaled according to the development of both the helpers and the helped. Among the Kikuyu of Kenya, 7–12-year-old sisters' primary responsibility is sibling caregiving. While young girls may assist with domestic chores, taking care of their brother or sister is the cultural norm (Leiderman and Leiderman 1974). Similarly, in the USA, African American and Latino families, especially single-parent families, expected siblings to provide future support and began delegating age-appropriate caregiving tasks from a younger age (Jewell and Stein 2002; Fields 2003).

Conclusion

Older children in hunter-gatherer societies have several responsibilities and assist parents with

domestic chores, gathering, and other productive work (Sear and Mace 2008). The assistance provided by female offspring lessens the mother's workload and has beneficial outcomes on the survival of a younger brother or sister. Notably, the beneficial effect of older children is moderated by age and gender of the older brother or sister, birth spacing, need for childcare, availability of resources, and alloparents.

Definition

One of the most consistent predictors of intimate partner violence (IPV) perpetration in prior research is a history of abuse, particularly within the family of origin. However, not all victims of child maltreatment go on to perpetrate violence within their intimate partnerships. A number of theoretical explanations help distinguish who may be most at risk for perpetuating this “cycle of violence.”

Introduction

Historically, intimate partner violence (IPV) has often been viewed as a primarily male-perpetrated phenomenon. However, research in recent years has demonstrated that women also perpetrate violence against their loved ones. National surveys estimate that more than one in three women and more than one in four men have experienced rape, physical violence, or stalking by an intimate partner in their lifetimes (CDC 2010). In community surveys specifically, where less severe forms of violence, often referred to as “common couple violence,” are studied, it is often found that women perpetrate violence at rates equivalent to or even higher than men (e.g., Kaufman-Parks et al. 2017). In order to reduce IPV perpetration and its associated costs to victims, perpetrators, and society at large (e.g., CDC 2010), it is

imperative to understand the potential factors that increase the risk for such violence.

Prior research has documented a number of negative sequelae of childhood abuse and neglect. One of the most frequently researched consequences has been coined the “cycle of violence” hypothesis, whereby it is presumed that individuals who are abused as children grow up to face an increased likelihood of perpetrating violence toward their loved ones. Supporting this hypothesis, past empirical research has documented associations between harsh physical discipline and physical abuse of children and subsequent IPV perpetration throughout both adolescence and adulthood (e.g., Capaldi et al. 2012). Yet, research has also demonstrated that exposure to violence during childhood does not lead in a deterministic fashion to violent behaviors, including IPV perpetration, in later life (e.g., Smith et al. 2011). Rather, it appears that accounting for potential mediating factors is essential if we are to understand why individuals with a history of child abuse are more likely to engage in IPV (e.g., Capaldi et al. 2012). A number of theoretical explanations lend insight into these potential mediating factors, including individuals’ attitudes and beliefs, the ability to develop and maintain healthy attachments with others, cognitive decision-making processes, personality traits and disorders, genetic or neurophysiological risks, and adoption of specific life history strategies.

Social Learning Mechanisms

Social learning theorists argue that attitudes and behaviors are acquired through processes of observation, learning, and reinforcement with key social agents (Bandura 1977). As part of the natural aging and socializing processes, children observe the behaviors of key figures in their lives and encode their observations. At a later time, they may copy or imitate these observed behaviors, which are then reacted to by others. If others reinforce the newly performed behavior through praise or reward, the child is likely to continue performing the behavior. If reactions by others are negative, continued performance of the behavior

is likely to decline or cease entirely. Accordingly, because the family is one of the first and main socializing agents for most individuals, relationships between parents and between parents and children provide models for how individuals should behave in relationships with others.

In the context of IPV, social learning theorists propose that children exposed to violence in their families of origin learn that hitting is an appropriate response to conflict with others. Upon entering intimate relationships as adolescents and adults, these individuals then often have limited resources for dealing with relationship conflict in constructive ways and resort to violence as a strategy for conflict resolution. They may also develop an expectation for violence in their own relationships or feel that violence is necessary to maintain control and power in their lives (Foshee et al. 1999; Kaufman-Parks et al. 2016). For example, in a community sample of young adult men and women, it was found that harsh physical discipline by parents (i.e., physical abuse) in adolescence increased the risk for IPV perpetration in young adulthood among both men and women. Moreover, while the risk of IPV also increased among all individuals when they experienced verbal conflict with their intimate partners, this was especially the case among individuals who had previously been maltreated (Kaufman-Parks et al. 2016). As concluded by the researchers, such findings demonstrated that individuals exposed to childhood physical abuse may have a lower tolerance for verbal aggression in their romantic relationships and react violently as a result.

Despite the evidence linking child abuse and later IPV perpetration, empirical research also has found that the vast majority of individuals exposed to violence in the family of origin do not report IPV in adulthood (e.g., Smith et al. 2011). Similarly, global endorsements of IPV in the general population are often relatively low (Simon et al. 2001). In other words, most individuals with a history of abuse still do not perceive violence as an acceptable way of dealing with conflict in their adolescent and adult intimate relationships. What accounts for whether abuse leads to the adoption of attitudes accepting of IPV may

thus rest in factors considered in combination with and external to childhood victimization experiences specifically. For example, analyzing the development of attitudes toward IPV, Copp et al. (2016) noted a positive, significant association between neighborhood poverty and attitudes accepting of IPV, even after accounting for exposure to violence in the family of origin via interparental violence and “coercive parenting” (i.e., physical abuse). Thus, IPV perpetration among those with a history of child abuse may be especially likely if they are also placed within a greater structural and cultural context (i.e., the neighborhood) that espouses violence as a normative, or at least justifiable, behavior.

It is also important to note that although most social learning explanations of IPV focus primarily on family of origin experiences, the process of learning continues throughout the life course. In other words, individuals’ attitudes toward and engagement in violence with intimate others may be influenced by those external to the family unit and in contexts beyond the childhood years. For example, prior research has indicated that association with peers who perpetrate violence increases risk for individuals’ own IPV perpetration (Capaldi et al. 2012). Relatedly, individuals who experienced controlling behaviors from partners in earlier intimate relationships are more likely to accept violence as a justified response, under certain circumstances, toward an intimate partner in subsequent relationships (Copp et al. 2016). Thus, IPV perpetration among those with a history of abuse may be especially likely if such individuals are exposed to peers and intimate partners who further reinforce violence as acceptable. Conversely, individuals who, despite a history of abuse, are able to surround themselves with others who reject the acceptability of violence may decrease their chances of later IPV perpetration. As noted by Giordano (2010), children are not only influenced by their environments but, because of human agency, are able to influence their environments. Although children are arguably much more constrained than adults in selecting their immediate environments, they may still have the power to attend more to some family members than others or to select role

models outside the family, who do not model and reinforce violence as justified or socially normative.

Interestingly, however, some prior research has indicated that even after accounting for a history of family violence and a number of additional potential risk factors (i.e., sociodemographic characteristics, IPV experiences in previous relationships, current relationship status and duration), women may be more likely than men to endorse the use of violence under a number of different circumstances (Copp et al. 2016). What accounts for this difference is not entirely clear, but it is possible that the general societal belief that female-perpetrated IPV is less problematic or more acceptable than males may lead women to minimize the harms associated with their violent behavior.

Attachment Theory

Prior research has found that children who are abused are more likely to describe relationships with others as threatening or painful, attribute hostile intentions toward social partners, and are less likely to establish or maintain social interactions overall (e.g., Wolfe et al. 2001). This association between childhood abuse and later relationship perceptions may be best understood through an attachment perspective. Attachment theory (Bowlby 1982) rests on the premise that individuals begin to form early cognitive models of relationships with others based on the interactions they have with their parents and other adult caregivers. These cognitive models often entail such notions of others as being predictable and trustworthy, of the self as being lovable and competent, and of relationships in general as being rewarding and worthwhile.

Building from this foundation and illustrating the relative stability of attachment styles throughout the life course, Bartholomew and Horowitz (1991) developed and tested a four-category model of attachment styles based on adults’ perceptions of self and expectations of intimate others. Three of the attachment styles reflected insecure attachments, and two of the three have

been found especially likely to lead to IPV perpetration (e.g., Dutton et al. 1994; Henderson et al. 2005). The first insecure attachment style linking childhood abuse to later IPV perpetration has been labeled “fearful” (Bartholomew and Horowitz 1991). Individuals with a fearful attachment orientation experience a sense of unworthiness and the expectation that others will be untrustworthy and rejecting. This insecure attachment style results when children place blame on both themselves and others for their caregivers’ physically abusive behaviors. However, despite this negative model of self and others, fearful individuals still desire social contact and intimacy. This seeming contradiction results in a chronic sense of frustration, as fearful individuals become enmeshed in, and simultaneously try to withdraw from, relationships with romantic partners due to continual anxieties over rejection and abandonment (Bartholomew 1990). The second style of attachment linking childhood abuse to IPV perpetration has been labeled “preoccupied” (Bartholomew and Horowitz 1991). Preoccupied individuals experience a sense of unworthiness but a positive evaluation of others. This attachment style results when children place blame solely on themselves for the abuse that they have incurred. Relationships with others are sought in order to increase preoccupied individuals’ sense of self-worth. Yet, entering these relationships with a negative view of self, preoccupied individuals are as equally anxious about potential rejection and abandonment as their fearful counterparts. They are only differentiated from fearful persons in their positive evaluation of others, making preoccupied individuals less likely to withdraw from partners or blame partners for their anxieties.

How insecure attachment styles may lead to IPV perpetration can largely be understood as a consequence of negative emotional states (Dutton et al. 1994; Goldenson et al. 2007). For example, in a study of 120 men referred to treatment for wife assault, Dutton et al. (1994) found that both preoccupied and fearful men scored higher on levels of jealousy, borderline personality organization, anger, and trauma symptomology. More specifically, due to insecurely attached individuals’ hypersensitivity to rejection and

abandonment, fearful and preoccupied individuals are much more likely to experience romantic jealousy in their intimate relationships. Faced with the anticipated or perceived loss of their romantic partners, these individuals then attempt to regain partners’ attention and restore their relationships. However, their ability in doing so is limited as a result of dysfunctional parenting practices rooted in violence, which were unlikely to convey the social skills necessary to handle relationship problems in constructive ways. These limited social skills, combined with the trauma symptoms associated with a history of childhood abuse, then lead to increased anger and the potential for violence as an outlet for such anger. Illustrating that such processes are not confined to male perpetrators, a study of 33 female offenders receiving mandated treatment for IPV perpetration indicated that female offenders reported less attachment security, more trauma-related symptoms, and more personality psychopathology than did a clinical comparison group of women who had not engaged in IPV perpetration (Goldenson et al. 2007).

From an attachment theory perspective, these findings demonstrate that IPV perpetration may be a reaction to romantic partners analogous to the angry behavior of a child who has been separated from their caregiver (Dutton et al. 1994; Henderson et al. 2005). Although the consequences of IPV perpetration for romantic relationship functioning generally are not positive, they do often represent an active attempt on the part of perpetrators to maintain or improve relationships they perceive to be in danger. Thus, for those with a history of childhood abuse, IPV perpetration may be likely if individuals also suffer from attachment insecurities.

Social Psychological Processes and Personality Traits

Complementing both social learning and attachment theories, the social information-processing (SIP) model argues that childhood abuse may lead to IPV perpetration in adulthood through SIP deficiencies. Originally formulated by McFall (1982)

to describe social skills among the general population, Holtzworth-Munroe (1992) applied this model to martially violent men specifically, given many therapy programs' focus on addressing social skills deficits as a strategy to treat domestic violence. In later years, recognizing that many of the pathways leading to IPV perpetration may be similar among men and women, this model was later applied to domestically violent women as well (e.g., Fite et al. 2008).

According to McFall (1982), social skills are acquired and performed in a three-stage process. In the first stage, individuals receive and interpret incoming social stimuli, a process known as "decoding." Once decoded, individuals must choose an appropriate response to the social situation. This requires individuals to think of all the available potential ways in which they can respond, determine the response type that best fits the situation under examination, and select the behavior from their behavioral repertoire that best reflects their desired response. This process is referred to as "decision-making." In the final stage, labeled "enactment," individuals must execute their chosen response and monitor the situation to determine whether their response had the desired impact.

For individuals with a history of abuse, there may be breakdowns in the SIP stages that increase the risk for violence in a number of given social situations. For example, in the first stage, and in line with attachment theories (Bowlby 1982), individuals may misinterpret social situations due to various cognitive deficits, including unrealistic expectations, faulty attributions, and irrational beliefs (Holtzworth-Munroe 1992). For abuse survivors, who are likely to view others as untrustworthy and relationships as unrewarding or threatening (e.g., Wolfe et al. 2001), such cognitions might include being hypervigilant toward hostile social cues, perceiving harm, or ill-intent in situations where none exists. Similarly, and in line with social learning theories (Bandura 1977), individuals with a history of abuse may be unable to produce nonviolent response options in the decision-making stage of the SIP model. They may also perceive violent options as superior in producing the desired situational outcome

(Holtzworth-Munroe 1992). Intuitively, each of these breakdowns would be likely if individuals were exposed to violence and come to see violence as an acceptable, or at least justifiable, behavioral response.

Using data from the longitudinal Child Development Project, Fite et al. (2008) provided empirical support for using SIP models to understand IPV perpetration. Specifically, the researchers analyzed whether SIP models mediated the relationship between witnessing interparental relationship conflict during childhood and children's own romantic relationship conflict in young adulthood. Among children who had witnessed interparental relationship conflict, there were SIP breakdowns in both response generation and response evaluation stages, and these breakdowns partially mediated the intergenerational transmission of relationship conflict. In other words, witnessing interparental conflict during childhood inhibited individuals' abilities to generate constructive, non-conflictual social responses when interacting with romantic partners in young adulthood. They were also less able to effectively evaluate the potential outcome of their chosen (and often conflictual) responses. Importantly, no significant gender differences were found; both young adult men and women were equally affected by interparental conflict and SIP deficits in their own romantic relationships.

In addition to potential cognitive deficits, survivors of childhood abuse may suffer from personality disorders or exemplify certain personality traits that increase their risk for IPV perpetration. In regard to personality disorders, results from a community sample followed for over 20 years demonstrated that suffering from either Cluster A (i.e., paranoid, schizoid, and schizotypal) or Cluster B (i.e., borderline, narcissistic, antisocial, and histrionic) personality disorders mediated the effect of childhood family violence exposure and adult partner violence (Ehrensaft et al. 2006). The researchers concluded that individuals exposed to interparental violence were more likely to suffer from Cluster A personality disorders and that Cluster A disorders were suggestive of pre-existing symptoms of mistrust, suspiciousness, and distortions in cognitions, all of which

increased the risk for IPV perpetration. Similarly, individuals exposed to either interparental violence or childhood sexual abuse showed elevated Cluster B symptoms, which increased the risk of IPV perpetration due to individuals' propensity to engage in aggressive and antisocial acts.

In assessing personality traits, a considerable body of research has documented associations between anger and IPV perpetration. In a meta-analytic review of 33 studies, Norlander and Eckhardt (2005) found that IPV perpetrators, compared to nonviolent men, consistently reported higher levels of anger and hostility, and anger levels also helped to distinguish men in low-moderate and moderate-high IPV relationships. Accordingly, a number of hypotheses have been put forward to understand the connection between anger and IPV, given the recognition that anger does not always lead to aggression. As one example, some scholars have argued that anger may reduce inhibitions against violence, either by aiding in the justification of violence as a viable response option or by disrupting cognitive processes that would defend against a violent response (Norlander and Eckhardt 2005). Each of these propositions, in turn, builds upon social learning and SIP theories, where individuals with a history of abuse already face greater likelihood of accepting violence as justified.

Importantly, while most of the research on anger and IPV to date has focused on male perpetrators, a comparably smaller body of research indicates that female perpetrators may also experience a strong disposition toward angry feelings, often referred to as "trait anger." For example, in a study of 80 women arrested for domestic violence, Shorey et al. (2011) found that both traits anger and impulsivity were significantly associated with women's physical and psychological aggression toward intimate partners and that trait anger mediated the relationship between impulsivity and aggression perpetration. Taken together, these findings indicate that individuals with abuse histories may be more likely to perpetrate IPV in adulthood if they also experience SIP deficiencies, suffer from certain personality disorders, or have higher state-trait anger.

Neurophysiological and Genetic Explanations

To date, sociological and psychological theories have dominated the literature in understanding intergenerational linkages of intimate violence. Yet, in recent years, some scholars have argued that attention be paid to potential neurophysiological and genetic explanations. Such explanations compliment more traditional IPV theories, as it is likely that individuals' physiology interacts with such things as expectations about and attitudes toward violence, emotional regulation, and social skill deficiencies (Margolin et al. 2016). Accordingly, a number of physiological and genetic factors may help to explain why some, but not all, individuals who were abused as children grow up to perpetrate violence against romantic partners.

One potential neurophysiological link between a history of abuse and IPV perpetration is the hypothalamic-pituitary-adrenocortical (HPA) axis (Margolin et al. 2016), which regulates many bodily processes, including reactions to stress, and the regulation of moods and emotions. Exposure to early life stressors, such as childhood abuse, may lead to the dysregulation of the HPA axis. In turn, HPA reactivity, specifically in regard to cortisol activity, has been linked to aggression and hostility in adult intimate relationships. For instance, neuroimaging research conducted by George et al. (2004) demonstrated that abusive men had lower cortisol levels, resulting in hypersensitivity to social stimuli, including certain looks or critical statements from romantic partners.

In addition to the more indirect HPA dysregulation processes which may result from early exposure to violence, brain structure and functioning may be affected by childhood abuse more directly via traumatic brain injury. Severe childhood abuse may result in traumatic brain injury, later increasing the risk for IPV perpetration. Prior research has reported that abusive men have higher rates of head injury, with rates ranging between 40% and 62%, compared to an estimated 6% in the general population (Howard 2012). The orbitofrontal and anterior temporal lobes are the most common sites of brain contusion and

laceration. In turn, the orbitofrontal cortex is the area of the brain that maps rewards and punishments through cortical activity. When damaged, this can lead to deficient social competencies in the arenas of judgment and behavior, the ability to experience certain moods and emotions, and the capacity for realizing others' thoughts and feelings.

Finally, some research has noted that genetic susceptibility may help to differentiate between maltreated children who do and do not go on to become aggressive and violent in adulthood. Deficient monoamine oxidase A (*MAOA*) gene activity, which metabolizes neurotransmitters such as norepinephrine, serotonin, and dopamine, may predispose individuals to respond hyperreactively toward perceived threats in incoming social stimuli. Examining the effects of maltreatment status and *MAOA* activity on antisocial behavior, Caspi et al. (2002) conducted research among a sample of individuals assessed from early childhood (age 3) to young adulthood (age 26). When measured by itself, *MAOA* activity had no significant effect on antisocial behavior. However, among maltreated children, low *MAOA* activity predicted four antisocial behavioral measures: adolescent conduct disorder, adult violent criminal convictions, self-reported disposition toward violence, and informant-reports of antisocial personality disorder symptoms. Taken together, these findings lead to the conclusion that, among individuals with a history of abuse, certain neurophysiological deficiencies and genetic susceptibilities may further increase risk for perpetrating IPV in later life. Importantly, while the vast majority of neurophysiological and genetic research on IPV perpetration to date has been conducted among men, it is not implausible that such findings may also hold true for women.

Evolutionary Perspectives

Integrating social psychological and biological models, contemporary evolutionary scientists have proposed a life history strategy for understanding the connections between a history of childhood abuse and IPV perpetration in

adulthood. Life history theory is based on the premise that all living organisms face trade-offs in dividing their energy and effort between important survival goals, given that resources for survival and reproduction are finite (Kaplan and Gangestad 2005). The trade-offs that organisms, or individuals, make determine what is referred to as their "life history strategy," which exists on a fast to slow continuum. A fast life strategy entails making decisions based often on immediate gratification or short-term gain with little investment in long-term maintenance or growth. Fast life strategies are most often exhibited in environments that are considered dangerous or limited in resources. Because individuals in these environments experience shorter life expectancies, it pays more to invest in short-term gains instead of devoting time and energy into long-term planning and relationships. Sexual promiscuity and aggressive behaviors are commonly cited examples of a fast life strategy (e.g., Brumbach et al. 2009). Conversely, a slow life strategy entails making long-term investments that signify the preservation and progression of both physiological systems and "embodied capital" (e.g., knowledge and skills) (Kaplan and Gangestad 2005). Slow life strategies are commonly adopted in environments that are considered safe, stable, and plentiful in resources. Delaying reproduction until individuals are able to sufficiently provide for their offspring financially and emotionally is one example of a slow life strategy.

Importantly, a great degree of variability exists between individuals' life history strategies; and some scholars have argued that such variation may be accounted for by the family. For example, building on Bowlby's (1982) attachment theory, Belsky et al. (1991) suggested that the family environment is central to the social, emotional, and behavioral development of children. Accordingly, when family functioning is disrupted through environmental uncertainty and its consequent stressors, secure attachments between parents and children become damaged, leading children to adopt internal working models of relationship uncertainty. In turn, internal working models of significant others and the environment overall as uncertain and unpredictable increase the

risk for adoption of a fast life history approach. Analyzing data from the National Longitudinal Study of Adolescent and Adult Health (Add Health), Brumbach et al. (2009) provided empirical support for the importance of family in predicting young adults' life history strategies and a wide variety of life history traits (e.g., mental and physical health, sexual attitudes and behaviors, social deviance). Of most relevance to the study of IPV perpetration, the researchers found that environmental harshness during adolescence via exposure to violence was predictive of adolescent delinquent behavior. Similarly, environmental unpredictability, which measured frequent changes or ongoing inconsistency in individuals' childhood environments (e.g., parents failing to provide for basic needs, being removed by social services), was predictive of delinquency during young adulthood. In turn, adolescent and young adult delinquency was associated with other negative life history traits (e.g., mental and physical health, sexual attitudes and behaviors) indicative of fast life history strategy. Considering that aggression is one potential form of delinquency, individuals who (unconsciously) adopt a fast life history approach as a result of childhood abuse may be more likely to perpetrate IPV in adolescence and young adulthood.

Conclusion

Being a victim of or witness to violence in early life is a significant risk factor for perpetrating violence throughout the life course. Yet, most individuals with a history of abuse still do not become violent toward romantic partners in adulthood. As demonstrated throughout, a full understanding of this variance and the complex processes by which intergenerational violence is transmitted requires a multifaceted theoretical framework. Specifically, those individuals exposed to violence in childhood via child maltreatment or interparental violence may be especially likely to perpetrate IPV in adulthood if they are also placed in multiple contexts that model violence as an appropriate way of dealing with conflict. These contexts may include associations

with deviant peer groups and intimate partners, as well as more structural contexts such as neighborhoods (Capaldi et al. 2012; Copp et al. 2016). Relatedly, when combined with a history of abuse, attachment insecurities (Dutton et al. 1994), cognitive difficulties (Holtzworth-Munroe 1992), personality disorders or certain personality traits (Ehrensaft et al. 2006; Shorey et al. 2011), neurophysiological deficiencies (Margolin et al. 2016), genetic susceptibilities (Caspi et al. 2002), and adoption of a fast life history strategy (Brumbach et al. 2009) may each further increase the risk for violence toward a romantic partner in adulthood.

The bond between two persons, often between an infant and his/her caregiver.

Ethological Beginnings

Ethologists were the first to notice that all species exhibit particular biologically programmed attachment behaviors. These behaviors ensure that adults will care for their young and increase their chances of survival. Current attachment theory was formed by examining the research conducted by ethologists on animals. For instance, an ethologist, Konrad Lorenz (1935), studied imprinting in ducklings and goslings. Imprinting is a phenomenon in which a duckling or gosling will follow a moving object. Imprinting is believed to be innate and most likely to happen during a sensitive period shortly after birth. Harry Harlow's (1958) extensive research with infant and mother monkeys also paved the way for current attachment theory. Harlow separated infant monkeys from their birth mothers and placed them with surrogate "mothers." Infant monkeys were then raised by either a wire-mesh mother who supplied them with a bottle of milk or a wire mother wrapped in a soft cloth. Harlow found that monkeys spent much more time with the cloth mother, especially when the infant monkeys were scared or when they were encountering new surroundings. Harlow's studies directly tested the hypothesis that young infants form

attachments to their mothers because they are the source of food, rather than affection. In fact, the behavioral viewpoint at the time proposed that mothers should limit their affection toward their children (Watson 1928/1972). Harlow's finding that infant monkeys used the cloth mother as an attachment figure emphasized the importance of contact comfort to the attachment process. In addition, Harlow's work found that infant monkeys would use their cloth mothers as a secure base when exploring new situations.

Bowlby's Attachment Theory

Basing much of his work on imprinting and non-human primate studies, John Bowlby (1958) is credited with introducing the notion of attachment from an ethological perspective to the field of developmental psychology. Bowlby proposed that attachment is a bond between an infant and caregiver which increases the likelihood that an infant will survive. Human infants, in particular, are born depending on their caregivers for survival. Bowlby proposed that attachment evolved to keep the infant safe from predators and exposure to outside elements. To ensure that the infant survives, he/she must exhibit behaviors that will elicit attention from a parent and create a need to keep the infant safe. These attachment behaviors can be as simple as a smile, a coo, or a babble early on. As infants get older, they are more likely to show proximity-seeking behaviors such as crawling, walking, following their caregivers, and using visual social referencing. Developmental psychologists believe that this proximity-seeking behavior is later related to separation and stranger anxiety as infants begin to become more independent of their caregivers. It is also believed that evolution has created a biologically predisposed need for caregivers to want to attend to their young. Adults find that they want to attend to their infants' smiling and babbling and to keep them safe. Lorenz (1943) even discussed how the cuteness of many baby mammals, including humans, draws in adults and elicits caregiving behaviors. Unlike imprinting, Bowlby (1969) believed that human attachment develops

gradually. It is not until approximately 6 to 9 months of age that the infant discriminates and prefers to remain in contact with his/her attachment figure. The final stage of his four-stage theory, goal-corrected partnerships, does not happen until the infant is at least 3 years of age. Attachment does not fully develop until the infant has the communication skills necessary to foster a reciprocal interaction between caregiver and infant in which each understands the other person's emotional responses. Bowlby also proposed that an important cognitive mechanism arises as a result of the infant and parent attachment relationship. He called this mechanism an internal working model, a memory of the attachment bond that creates a cognitive representation of the infant's relationships with others. If the attachment relationship was one in which the parent was consistent and responsive to the child's needs, the infant would have an internal working model that people can be trusted. If instead the parent was inconsistent, insensitive, and unresponsive, the child would have a distrustful internal working model for relationships.

Empirically Measuring Attachment

The notion of attachment is a difficult emotional construct to define. Mary Ainsworth (Ainsworth 1973) is credited with creating an empirical examination to describe the attachment bond between a caregiver and infant/toddler between the ages of 12 and 24 months. Infants and caregivers are observed in a Strange Situation paradigm, especially identifying the attachment behaviors of proximity-seeking and using the caregiver as a secure base (Ainsworth et al. 1978). The Strange Situation paradigm is a series of eight contextual episodes which places the infant and caregiver in various situations, each lasting 3 min. In each situation, the infant interacts with his/her caregiver or a stranger or is left alone in an unfamiliar room. Ainsworth classified an infant/caregiver attachment by closely watching for how the infant uses the caregiver as a source of comfort. Secure infants (sometimes referred to as Type B), when distressed, will turn to their caregivers for support

and comfort. They will exhibit proximity-seeking behaviors either visually or physically and explore the room after checking in with their caregivers. Caregivers will also reciprocally meet the needs of their infants, whether it be for comfort or to foster independence. Connecting this to Bowlby's ideas, it is hypothesized that securely attached infants have developed a trusting internal working model after many months of consistent and sensitive parenting responses. The other three categories of attachments are classified as insecure. Infants with insecure-resistant/anxious-ambivalent (sometimes referred to as Type C) attachments respond to the strange situation by exhibiting anxious, resistant, and contradictory behavior toward their attachment figure. They may, at one point, seek comfort from the parent by clinging but moments later show anger and push the parent away. Infants with insecure-avoidant (sometimes referred to as Type A) attachment show little emotion and distress when separated from their parent and disengage and avoid contact when they return. Empirical research has since discovered an additional attachment style category, the disorganized (sometimes referred to as Type D) attachment (Main and Solomon 1986). Infants who exhibit disorganized attachment behaviors may exhibit anger, calm play, cry hysterically, stare blankly, or sometimes freeze or move slowly. More recent developmental theorists have proposed another classification, reactive attachment disorder, for children who have been significantly maltreated or institutionalized (Zeanah et al. 2004).

Definition

Dominance theory in ethology is concerned with how dominance hierarchies develop and function within human and animal societies in relation to the operation and maintenance of social status, behavioral strategies for survival and reproduction, and gaining preferential access to resources in competitive social situations.

Introduction

This entry will start with a history of dominance theory in ethology, before documenting the history of the understandings of socially stratified relations as they have been developed in some other subjects such as sociology and philosophy. It will then consider component concepts of Denise Cummins' more recent account of dominance hierarchies in more detail, as it was developed as part of the wider evolutionary psychology paradigm.

In terms of a definition, a dominance hierarchy, otherwise known more colloquially as a pecking order or a rank order, is simply a well-defined set of priorities defining the access of different individuals to desirable resources. High-ranking individuals have priority for access to desirable resources over low-ranked individuals, but specific dominance hierarchies often involve complex sequences of priority for various individuals in relation to different types of resources. Higher-ranking individuals are usually more successful in reproductive terms than lower-ranking individuals but this may not always be the case, as lower-ranking individuals can use non-aggressive and/or deceptive means to achieve their reproductive aims (Turner 1992, p. 148).

Dominance hierarchies are both conceptually and organizationally distinct from bureaucratic or administrative hierarchies, even though they do share some common characteristics with them. Bureaucratic or administrative hierarchies are formally fixed structures of dominance and subordination in which individuals occupy specific roles at specific times, and in which authority is formally stratified and the division of labor clearly defined (Jaques 1991). Dominance hierarchies on the other hand, as will be seen, are more organic and less formal than bureaucratic hierarchies, and they allow for greater fluidity in the specified roles and greater flexibility in the hierarchical relationships.

The idea that human societies are hierarchically stratified is, of course, nothing new, the concept of the class hierarchy being found in the work of various nineteenth-century and twentieth-century social theorists such as Karl Marx and

Max Weber (Barnett 2009, p. 122). However, since the notion of a class hierarchy is potentially distinct from dominance hierarchies and bureaucratic hierarchies, the historical origins of dominance theory in ethology needs to be considered.

Origins of Dominance Theory (Ethology)

The origins of the hypothesis of an evolutionary link between human and animal mental states and behavior is often attributed to Charles Darwin (1874 [1871]), but its historical origins goes back much further than this. John Gregory's *A Comparative View of the State and Faculties of Man with Those of the Animal World* explicitly paralleled the human mind both as a material system of instincts in parallel with the human body, and alongside the instincts of animals (Gregory 1766 [1765], pp. 4–7).

Gregory declared in proto-Darwinian fashion that “one [animal] species often runs into another so imperceptibly, that it is difficult to say where the one begins and the other ends,” and he declared that the mental faculties of different species of animals were all “well adapted to the particular sphere of action which Providence has allotted them” (Ibid., 8). In addition, he believed that the scientific enquiry “into the Instincts that are natural to Mankind” should be conducted alongside the study of “the analogous Instincts of other Animals” (Ibid., 16).

While neither Gregory nor Darwin discussed dominance hierarchies explicitly, Darwin did describe what he called “the law of battle” that operated between male animals, with the victors in these battles being characterized as conquerors (Darwin 1874 [1871], pp. 500–514). In a section of *The Descent of Man*, he explained that:

When many males congregate at the same appointed spot and fight together, as in the case of grouse and various other birds, they are generally attended by the females, which afterwards pair with the victorious combatants. (Darwin 1874 [1871], p. 49)

Although in this passage the concept of dominance was not explicitly outlined, it can be suggested that dominance relations were implied through the idea of the victorious combatants in

fight. However, the idea that “the Battles of certain [Male] Animals for the Possession of their Females” was common in nature goes back to well before Darwin, at least as far as J.J. Rousseau (1761, p. 85).

The concept of a dominance hierarchy in its ethological sense was first explicitly studied in the early 1920s in relation to the behavior of chickens (Schjelderup-Ebbe 1921), which is how the term pecking order (*Hackordnung*) originated. The pecking order of chickens is established most significantly in relation to feeding and mating behavior. As has been explained:

When strange[r] chickens are put together, they will at first fight intensively. Each animal will fight every other animal and victory or loss will determine its future standing. A chicken that has lost a fight will remember the victor and avoid it in the future. The victor usually is the stronger animal, but agility, perseverance, and aggressiveness are also of importance. (Eibl-Eibesfeldt 1975, p. 391)

The term pecking order came into being because chickens fight mainly by pecking at other chickens with their beaks. Once the pecking order is established, fights then only occur occasionally, and most of the time the chicken social structure remains peaceful. The pecking order determines which chickens have priority access to any newly-available resources such as food sources and mates.

However, the notion of a pecking order, if not the term itself, goes back at least as far as the early eighteenth century, where peck sparring between young cockerels, and the resultant “well ordering of the Cocks in these their early heats” of battle, was duly noted (Howlett 1709, p. 42, 48). The pecking instincts of various different birds were discussed in detail at the end of the nineteenth century (Morgan 1896, pp. 36–44), and hierarchies within Eskimo dog sledge teams were noted by anthropologists at around the same time (Boas 1964 [1888], p. 125). Dominance hierarchies among both jackdaws and mice were studied more formally by ethologists in the 1930s (Lorenz 1935; Urich 1938), and the effects of social conditioning on dominance behavior began to be studied in the 1940s (Ginsburgh and Allee 1942).

The link between territorial groupings and dominance hierarchies was considered by various authors as early as the 1920s (Howard 1920; Allee 1926). Some animal dominance hierarchies are confined in their active operation to certain marked geographical areas, the individual control of which has been clearly established through previous ranking contests amongst individuals located in the area under dispute (Blount 1990, pp. 430–431). As has been explained:

Dominance behavior can be conveniently viewed as the analog of territorial behavior in which a group of animals coexist within one territory. The result is that one of them, the equivalent of the territory holder, comes to dominate the others ... The expression of hierarchies may shift with the spatial position of the animals. (Wilson 1971, p. 196)

One of the first more general accounts of rank order in the psychology literature in the 1930s linked together behavior, status, and feelings of social dominance (Maslow 1937).

The connection between rank order, constant mating provocation, and the growth of the neocortex region of the brain began to be investigated in the ethology literature in the 1960s. The need to mediate between sexual and aggressive behaviors was seen as a crucial driver in the growth of Hominid brain size, with dominant animals being characterized as those that could hold their aggressive and sexual instincts in most effective equilibrium (Chance 1967). Also in the 1960s, dominance hierarchies among crickets were studied (Alexander 1961).

However, there is an important difference between the dominance hierarchies of crickets and those of chickens. In the case of chickens, individual hens remember which particular hens they have previously beaten in fights, whereas individual crickets only remember whether they have won or lost across a sequence of fights.

The concept of a dominance hierarchy became very well established across the ethological literature on animal behavior and many studies of specific animal dominance relations were published (see Richards 1974 for a discussion of dominance assessment). The concept of a pecking order eventually migrated to other academic subjects. For example, the literature on the structure

of corporate finance (Frank and Goyal 2003) and the literature on the sequence of biochemical reactions (Buettner 1993, both developed their own versions of a pecking order theory.

The related concepts of the teat order and the leap order were then proposed. The teat order refers to the sequence in which piglets get to suckle their mother's milk (Jeppesen 1982), while the leap order refers to a separate form of physical aggression (leaping) that chickens use in addition to pecking (Rajecki 1991). However in addition to its prevalence in the ethology literature, the idea of dominance structures has also been a key part of the social science tradition for a very long time.

The History of Dominance Theory in Human Societies

When stranger human beings are first put together, they do not usually fight each other in order to determine a future pecking order, like chickens do. However, occasionally a few do exhibit similarly aggressive behavior:

Mentally retarded [sic] boys who stayed together in a fairly large room initially fought for certain territories. When at last everyone had claimed a spot, quarrelling became rare ... Each had his place and knew that there he would be left in peace. (Eibl-Eibesfeldt 1975, p. 505)

Even though such first-contact physical aggression is rare among human beings (Esser 1968), when they are first put together, humans do instinctively evaluate each other in terms of a range of different qualities such as looks/beauty, physical strength, size, exhibited wealth, age, sexual orientation, and so on, in order to determine preliminary evaluations of various qualities such as perceived rank order and potential future relationship function (friend/foe; predator/prey; sexual partner/platonic).

Various types of hierarchy in human societies have, in consequence, been documented for many centuries. For example, the ruling Turkish political hierarchy, composed of the Grand Seigneur, his chief councillor the Great Vizier, then the Lords of Lords and then the provincial Sanzacks, was

documented in the UK in the late seventeenth-century (Shirley 1683, pp. 384–385). This political hierarchy could be conceived of as a dominance hierarchy. The familial dominance hierarchy was one of the first hierarchies to be explicitly identified as such in terms that are very close to the contemporary ethological meaning: Thomas Hobbes described what he called “paternal dominion” in the mid-seventeenth century (Hobbes 1983 [1651], p. 197).

Within the social science tradition in the West, one of the earliest works explicitly on social hierarchy in human societies was John Millar’s *Observations Concerning the Distinction of Ranks in Society* (1771), which argued that over time, social authority tended to become less concentrated and more dispersed across society as a whole. Adam Smith was more pessimistic than Millar, arguing that the idea of submitting to higher ranks was a doctrine of nature that was difficult to over-ride (Smith 1976 [1759], p. 53).

By the early twentieth century, the nature of social authority and bureaucratic hierarchy was being investigated by sociologists such as Max Weber, who distinguished between various different types of authority: rational/legal, traditional, and charismatic authority (Weber 1947 [1922], pp. 300–301). Regarding the functioning of bureaucratic hierarchies, Weber declared that:

The organization of offices follows the principle of hierarchy; that is, each lower office is under the control and supervision of a higher one. Hierarchies differ in respect to whether and in what cases complaints can lead to a ruling from an authority at various points higher in the scale, and as to whether changes are imposed from higher up or the responsibility for such changes is left to the lower office. (Weber 1947 [1922], p. 303)

Weber outlined that different hierarchies could sometimes employ different types of authority in tandem, for example, in the system of hereditary charisma. Occasionally, Weber’s work was drawn upon by those studying animal dominance hierarchies (Chapais 1991, p. 191). In the first half of the twentieth century, the philosopher Bertrand Russell identified power as being the fundamental

concept of social science, but Russell’s work on this topic was not influential within the social sciences (Russell 1938, p. 10).

As has been demonstrated in this section, although various types of social, political, and administrative hierarchies were considered by sociologists such as Millar and Weber and by philosophers such as Russell, the concept of a dominance hierarchy as a type of pecking order generally remained limited to the ethological literature for much of the twentieth century, until it was taken up directly by various evolutionary psychologists such as Denise Cummins at the end of the century.

Cummins on Dominance Hierarchies

A few studies applying the ethological concept of dominance hierarchies to humans had been published prior to Cummins, but, with one notable exception (Omark et al. 1980), these studies were usually isolated examples with very specific foci, for example, school playground hierarchies or hierarchies in psychiatrically hospitalized boys (Esser 1968). Cummins was, therefore, in the mid-1990s the first to attempt a more general application of dominance theory to human societies using evolutionary psychology as the overarching theoretical framework. As she explained about the fundamental impetus to her work on dominance theory:

... a look at human history shows quite unequivocally that humans have the unfortunate tendency to organize themselves into dominance hierarchies at both local and global levels. A monarchy, with its social stratification of power and status, is a dominance hierarchy. Indeed, much of human history is a careful record of intrigues and wars aimed at gaining or limiting domination of territory and resources ... The struggle for survival through competition and cooperation with members of one’s own species is as old as life itself. If the data on social norm and theory of mind reasoning show us anything, it is that the winners are most likely to be those with the capacity to exploit or route the constraints of the dominance hierarchy. (Cummins 1998, pp. 45–46)

As will be seen, by “route the constraints of the dominance hierarchy,” Cummins meant to manipulate it to an individual’s own benefit.

A dominance hierarchy is simply a social hierarchy that is governed by a set of rules that enshrine the various rankings that constitute it, e.g., that if *A* has priority over *B* for resource *x*, and *B* has priority over *C* for resource *x*, then *A* also has priority over *C* for resource *x*. As explained by Cummins:

Social living confers both costs and benefits to individuals . . . In hierarchical social groups, how these costs and benefits cash out depend a good deal on an individual's status. Consider that from a cognitive standpoint, a social hierarchy is, essentially, a set of *social norms*, that is, *rules that constrain the behavior of individuals depending on their rank* (Cummins, 2000). In human societies, these may be implicit or explicitly codified as regulations or laws . . . (Cummins 2005, pp. 681–682; italics in original)

The basic distinction between hierarchical and nonhierarchical societies (e.g., some aboriginal societies) is not that the latter are not constrained by any general social rules, but that in the former, adherence to social rules varies in a well-defined way according to an individual's position within the dominance hierarchy (Cummins 2005, p. 681).

How the set of rules that constitute the dominance hierarchy are established also varies for different animal species. For example, rank in chimpanzee hierarchies is not determined by physical size of the individual animal but instead by the formation and maintenance of alliances that provide support during any ranking contests (Cummins 1998, p. 34). In other animals (e.g., chickens), rank is determined mainly by fighting ability. As Cummins explained, in addition to physical abilities, “dominance hierarchies are supported by a collection of specific *cognitive functions*” such as rule learning, behavior forecasting, and alliance formation (Cummins 2005, p. 680). A central distinction here, therefore, is between physicality-based dominance hierarchies and prestige-based hierarchies, although sometimes a combination of both types is involved.

Regarding the origins of her approach, Cummins has cited work on both reciprocal altruism and the social context effect vis-à-vis reasoning tasks as the initial starting-points of her own work. As she explained, from reading the literature on how reasoning processes actually

functioned, she noted that “virtually all of them made reference to status hierarchies, and . . . social norms . . . It seemed apparent to me that status hierarchies were the crucible with[in] which much social intelligence adaptation evolved” (Private correspondence).

Therefore, Cummins' work can be seen as stemming less from the ethological approach to status hierarchies and more from the cognitive psychology tradition of understanding the influence of content effects on reasoning performance, as human social reasoning evolved in direct response to the need to navigate dominance hierarchies. The only partial precursor in this respect is the work of Michael Chance (1967).

Cummins argued that the higher reasoning capacity of human beings evolved in direct response to the pressure to cooperate and to compete with conspecifics within the set of dominance hierarchies that go to make up human societies (Cummins 1998, p. 30). This means that the main function of higher intelligence in human beings is not primarily to solve abstract or mathematical problems, but to solve problems associated with social behavior and the understanding of group dynamics. Successful functioning within dominance hierarchies requires the application of deontic reasoning, or reasoning about rights and obligations with respect to what individuals are permitted, obligated, and forbidden to do within these dominance hierarchies (Cummins 1996a, b, 1998, p. 39, 1999).

Cummins contrasted this deontic reasoning about social norms with indicative reasoning, or reasoning about what is factually true or false, and suggested that humans are “primed” for, or have evolved psychological mechanisms devoted to, responding to violations of these hierarchical social norms (or to cheating) by means of ongoing deontic calculations. One piece of evidence for the importance of deontic reasoning was that this form of reasoning emerges early in a child's development and operates separately from indicative reasoning, with children as young as three exhibiting behavioral sensitivity to transitive dominance hierarchies (Cummins 1998, p. 42).

Even so, some references to work on the social order of turkeys suggest that ethology was certainly

an influence on Cummins' approach (Cummins 1998, p. 34, 50; Watts and Stokes 1971). Hence, although her work on dominance hierarchies is an important part of the evolutionary psychology paradigm, it also fits to a significant degree within the comparative psychology tradition, which aims to understand the parallels between animal behavior and human societies (Vonk and Shackelford 2012; Romanes 1898 [1878]).

A modern form of the comparative psychology tradition, which Cummins' work can be said to resemble to a degree, is comparative developmental evolutionary psychology, which "integrates frameworks from developmental psychology and evolutionary biology" (Parker 1990, p. 3). It has been suggested that Darwin's approach to studying comparative cognition searched for human-like behaviors in animals (Shettleworth 2012, p. 529, 532); in which case, Cummins' work can be described as searching for animal-like behaviors in human beings. This would characterize it as drawing on the contemporary cognitive ethological tradition, or on the evolutionary comparative cognition framework.

Other Aspects of Dominance Hierarchies

Dominance hierarchies are not static structures but are open to challenge and are subject to ongoing conflicts and change, a fact that was acknowledged early on in the ethology literature (Lorenz 1935). They are dynamic structures in which some individuals challenge others above them in the hierarchy for greater resource-access rights and where established hierarchies can be reversed or overturned, at least for a period of time.

This dynamic property of dominance hierarchies is one important way in which they differ from bureaucratic or administrative hierarchies. It is certainly possible for individuals in bureaucratic hierarchies to be promoted or demoted, and therefore to change position within the hierarchy, but this is a formal process that follows fixed administrative procedures. Changes within dominance hierarchies are less formal and more open-ended, and are also subject to more frequent and ongoing challenges.

In addition, the dominance hierarchies of different species can have different levels of dynamism. In one species, the dominance hierarchy might only rarely be subject to challenge and experience changes only very infrequently, for example, after the death of a dominant individual, whereas in another species the dominance hierarchy might be subject to almost continuous challenge and in consequence experience very frequent changes in position.

Interestingly, dominance hierarchies are not always linear (or transitive) in function. For example, in most circumstances, if *A* has priority over *B* and *B* has priority over *C*, then *A* necessarily has priority over *C*, i.e., a simple linear relationship exists between *A*, *B*, and *C*. However, in other circumstances it is possible for non-linear (or non-transitive) hierarchies to develop. For example, a high-ranking individual *A*, who was dominant over both *B* and *C* because they had been victorious over them in previous fights, might then lose to *D* in a fight, *D* having previously lost to both *B* and *C*, possibly because *A* was temporarily weakened by their last fight. Then *A* would still be dominant over *B* and *C*, but would be below *D* in the hierarchy, even though *D* would still remain below *B* and *C* (Eibl-Eibesfeldt 1975, p. 391). It is likely that such non-linear hierarchies are often transient phenomena.

Sex Differences and Dominance Hierarchies

So far, the discussion about dominance hierarchies has been presented as if all individuals of the same species had the same nature, when in fact this assumption is certainly false. Males and females have, in some respects, very different natures (Davies and Shackelford 2008). One example of this is that *Homo sapiens* women tend to use subtler and more indirect means of conducting intra-sexual competition, in order to denigrate and defeat rivals, whereas men use more direct and physical means of intra-sexual competition. Put differently, women tend to use relational verbal aggression as a means of intra-sexual competition, whereas men tend to use

direct physical aggression (Cummins 2005, p. 691; Mavin 2008).

Other differences relating to sex have also been outlined in the literature. For example:

An important implication of men's stronger tendency to compete over status is that the male status hierarchy is steeper and has a more pinched distribution: that is, we find more men at both the highest and lowest end of the status continuum, while relatively more women lie in the middle of the hierarchy . . . Given their motivation to obtain status, men have been more eager to become leaders than women. (Buunk and Dijkstra 2012, p. 41)

However, just because there have been, historically, more male leaders than female, male leaders are not always superior to female leaders, and there are observable patterns that have been identified in the literature for when male and female leaders are preferred. For example, it has been suggested that female leaders are preferred in order to manage instances of intra-group conflict and competition, whereas male leaders are preferred in order to manage instances of inter-group conflict and competition (Ibid.).

Another aspect of dominance and sex differences is that there are three forms of dominance hierarchy that are found in the animal world: male-male hierarchies, female-female hierarchies, and male-female hierarchies. If male-male hierarchies were the first 'default' dominance hierarchies to be investigated in the 1920s, as was also implied in Darwin's notion of "the law of battle," then female-female dominance hierarchies began to be studied as separate phenomena in more detail in the 1960s (Kawamura 1965).

Male-female dominance hierarchies are heavily affected by the degree of sexual dimorphism present in the particular species in question. In species with no or low sexual dimorphism, male-female hierarchies are either ambiguous or mildly in favor of females. However in species with high sexual dimorphism, male-female dominance hierarchies usually operate strongly in favor of males. Female-female dominance hierarchies are often matrilineal, i.e., rank is transmitted from mothers to daughters, although they are not always so. Male-male dominance hierarchies are

often based on size and fighting ability but other factors such as skill at making cooperative alliances are sometimes also involved (Chapais 1991, pp. 199–200).

Conclusion

Historically speaking, the formal concept of a dominance hierarchy started out in the ethological animal behavior literature (in its "default" male-male form) in the early part of the twentieth century, before it migrated to various other subjects, then broadened out to include female-female dominance hierarchies, and was eventually adopted by evolutionary psychologists such as Denise Cummins at the end of the twentieth century. In this protracted adaptation process, the concept was transformed from its early more narrow "pecking order" meaning, which was initially confined to chickens, to a broader concept that could be applied to both other animal species and to human societies.

However, it is important to distinguish between the concept of a dominance hierarchy meant in its ethological sense, and other types of hierarchies such as class, administrative, or bureaucratic hierarchies. These latter types of hierarchy do share some features in common with dominance hierarchies, for example, that position within them is usually connected with an individual's status, but they also have some features that may differ from them, for example that positional changes are usually accomplished by more formal and/or bureaucratic means.

Although, as has been suggested, the importance of the class hierarchy for a long time involved "the profound influence which it exerts upon the intermarriage of different families," with legal penalties sometimes applying to illicit inter-class marriages (Fisher 1930, p. 210) – similar to how an individual's dominance hierarchy position usually affects their reproductive success – such strict marriage prohibitions are now no longer in place in most of the Western world. This may mean that class hierarchies are now less important

than dominance hierarchies in determining mating success in some instances.

Finally, one potentially interesting further extension of dominance theory might be to widen its scope beyond the intra-species level, as has been discussed in this entry, to the inter-species level, in order to investigate how some species may dominate over other species. As Darwin related, human beings are currently the dominant species in the world (Darwin 1874 [1871], p. 51), but all other species below them are not of equal rank with each other. How the long-term evolution of different species affects various inter-species dominance hierarchies might prove an illuminating topic.

Definition

In living organisms, inheritance is the sum of genetic and epigenetic characteristics transmitted from the previous generation to the offspring.

Introduction

From a historical perspective, inheritance is a multifarious epistemic object. Discussions of biological inheritance have crossed various eras leading to multiple explanations of the processes of hereditary transmission. Scholars have retraced the stages of the scientific debate on inheritance from the early modern theories of generation to modern molecular genetics. When considering the historical evolution of the debates on heredity, there are however shifts in meaning and conceptual transformations that must be tackled. Until the beginning of the twentieth century, the circumstances of conception, pregnancy, and development were not seen as separable from the processes of inheritance. Still in the mid-nineteenth century, the belief that the child was susceptible of acquiring likeness to a particular individual at the moment of conception was widespread among physiologists and physicians (Bowler 1989).

For many years, discussions of biological inheritance were meant to include a range of phenomena, i.e., social learning and cultural transmission, which started to be considered as specific – and often independent – levels of inheritance only between the nineteenth and the

twentieth centuries (Stocking 1968). Over time, theorists of inheritance assumed the existence of various physical substances responsible for the transmission of both body and behavioral characteristics and proposed different mechanisms of transmission. These were often explained through linguistic metaphors taken from diverse historical frameworks that mirrored social practices. For this reason, historians have put effort towards highlighting how the knowledge of inheritance cannot be disembodied from technological practices and cultural contexts (Müller-Wille and Rheinberger 2012). Accordingly, the periodizations of the history on inheritance must take into account not only the turning points in the history of biology but also how the study of heredity has developed in relation to other areas, absorbing elements from medicine, farming, breeding, cybernetics, and computer science.

Inheritance and the Theories of Generation

Terms such as “heredity” and “inheritance” were absent from the medical literature until the mid-nineteenth century. Yet the first methodical investigations of transgenerational biological traits date back to the early modern studies of embryological development, which revived the ancient Greek theories of generation and the atomistic view of reproduction within a context of scientific inquiry based on microscopic observation and empirical investigation.

The works of the French natural philosopher Pierre Louis Moreau de Maupertuis (1698–1759) best exemplify this approach. In *Vénus physique* (1745) and *Système de la nature* (1751), Maupertuis provided a statistical analysis of the inheritance of polydactyly focusing on its modes of emergence and frequency. According to his interpretation of embryogenesis, the fetus formed from the combination of elementary particles from both the female and the male germinal line, finding their way in the embryo through chemical affinities

and forces of attraction. Hereditary aberrations were thus explainable in terms of mechanical failures in the distribution of such particles (Lange and Müller 2017).

The stress on the similarities between parents and offspring, as well as the idea that generation stems from the blending of female and male semen, harked back to the Galenic theory of “double semen” and the atomistic doctrine of “pangenesi” originally supported by Hippocrates and Democritus. According to this hypothesis, each part of the body would produce, through duplication, particles that convey the mold of the somatic structures to the gonads. In this way, the mixing of the two germinal lines was meant to imply the union of the somatic history of the parents.

This model of inheritance was widely diffused among French natural philosophers of the middle eighteenth century. In *Histoire naturelle de l’homme* (1749–1804), Georges-Louis Leclerc de Buffon (1707–1788) used the observational data gathered by the anatomist Louis-Jean Marie Daubenton (1716–1800) and the biologist John Turberville Needham (1713–1781) to maintain the double semen theory and the idea that organic molecules congregate in the genitals preserving the essence of the body part where they had originated.

Historians have often regarded this model of inheritance as the foundation of the modern conception of hereditary processes (Roger 1963). Furthermore, it played a major role in the pre-modern disputes on generation, highlighting the limits of the preformation theories of development, according to which each individual existed preformed either in the maternal ovum (*ovism*) or in the male semen (*animalculism*). The preformation theory could not give account of the manifest similarities between the parents and offspring, as well as of hybridization. Such new evidence came to reinforce the doctrine of *epigenesis* already theorized by Aristotle (384 BC–322 BC), René Descartes (1596–1650), and William Harvey (1578–1657), which has become the standard view of development since the middle eighteenth century (Canguilhem et al. 2003).

Inheritance and Hybridization in Natural History

The growing interest in hereditary processes between the middle XVIII and the XIX centuries can be scrutinized from various perspectives. The study of the patterns and fluctuation of hereditary characters in the cases of hybridization was of primary concern in the Colonial era, since it intertwined with the knowledge of human pathology and anthropology, as well as with breeding and botanic practices. For instance, the conceptual distinction between constant and variable characters was connected with animal crossbreeding and the attempts to acclimatize exotic plants to the temperature of European botanic gardens (Müller-Wille and Rheinberger 2012).

The dichotomy between constant and variable characters also underlay the broader debate on morphological deviance in species description. According to Swedish botanist Carl Linnaeus (1707–1778), hybridization (*mixtura*, *generatio hybrida*, *generatio ambigena*) showed a definite pattern of traits in plants: the medullar substance and reproductive organs were a copy of the maternal line, while the external features resembled the male (Linnaeus 1760). As the director of the *Jardin des plantes* of Paris, Buffon regarded the domestication and acclimatization of plants and animals as one of the primary sources of biological “degeneration” which could lead to the production of new species.

Speculations on hereditary mechanisms became part of medical and veterinary studies of animal crossbreeding. Among the most discussed phenomena of heredity was *telegony*, i.e., the idea that the characteristics of previous mates can influence the hereditary constitution of the female parent. In his communication published in the *Philosophical Transactions of the Royal Society* (1821), George Douglas Earl of Morton (1761–1827) stated he had bred a chestnut mare and a quagga stallion and then observed that the offspring produced by the mare mated to a black Arabian sire was more plainly barred across the legs than even the pure quagga (Burkhardt 1979). Similar accounts appeared among veterinarians

throughout the nineteenth century. James Law (1838–1921), dean of the Edinburgh Veterinary School, maintained that the impregnated ovum impressed the tissue of the placenta with the sire’s characters, which were then transmitted to the subsequent embryos. The geologist Louis Agassiz (1807–1873) acknowledged telegony as a real fact in natural history and stated that the female horses, once they are impregnated, are irreversibly modified in their hereditary constitution (Greene 2009, p. 101).

Inheritance and Evolution

The attention towards hybridization, domestication, and acclimatization had a remarkable role in the shaping of the nineteenth-century evolutionary debate. In France, Jean-Baptiste de Lamarck (1744–1829) proposed a systematic synthesis of the doctrines of Maupertuis and Buffon. In the *Philosophie Zoologique* (1809), Lamarck exposed his doctrine of transformation stating that environmental circumstances could drive organisms’ habits towards new adaptive scopes. By means of nutritional and nervous fluid dynamics, habits modified organic structures as well as the germinal fluids, which, in turn, transmitted the modified pattern of fluid distribution to the offspring. Throughout the nineteenth century, such form of hereditary mechanism, commonly known as the theory of the inheritance of the acquired characters, ended up being regarded as a synonym of Lamarckism (Burkhardt 2013).

Charles R. Darwin (1809–1882) never denied the supplementary contribution of use-inheritance processes in evolution. In *On the Origin of Species* (1859), Darwin traced back inheritable variations to various laws, including the conditions of life and the use-inheritance factor:

Variability is governed by many unknown laws, of which correlated growth is probably the most important. Something, but how much we do not know, may be attributed to the definite action of the conditions of life. Some, perhaps a great, effect may be attributed to the increased use or disuse of parts. The final result is thus rendered infinitely complex. (Darwin 1859, p. 31)

However, Darwin highlighted the nearly indefinite outcomes of the external conditions:

All such changes of structure, whether extremely slight or strongly marked, which appear among many individuals living together, may be considered as the indefinite effects of the conditions of life on each individual organism, in nearly the same manner as the chill effects different men in an indefinite manner, according to their state of body or constitution, causing coughs or colds, rheumatism, or inflammation of various organs. (ivi, p. 3)

In *The Variation of Animals and Plants Under Domestication* (1868), Darwin exposed his provisional hypothesis of pangenesis to account for the inheritance of acquired characters. According to his interpretation, which was later expanded by William Keith Brooks in *The Law of Heredity* (1883), somatic cells produce minute and discrete particles he called “gemmules” which would be able to circulate throughout the body and finally congregate in the gonads.

However, the dispute on the physical basis of the inheritance of acquired characters took a multifaceted form in the years of the post-Darwinian debate. Among the alternatives to the discrete view of heredity was the so-called dynamic theory originally proposed by the German physiologist Ewald Hering. On the occasion of the 30th anniversary of the Imperial Academy of Natural Sciences of Vienna (1870), Hering stated that the nervous system could convey the nerve vibrations to the whole organism, including the genitals. These could transmit all the qualities of the organisms, including acquired habits and instincts, thus making the individual development a record of memory. In *The Perigenesis of the Plastidule* (1876), Ernst Haeckel (1834–1919) reified Hering’s analogy between heredity and memory postulating the existence of the *plastiduels*, the hypothetical basic units of living matter whose wavelike movements, activated by external stimuli, transferred their acquired memory to the offspring.

The analogy between heredity and memory spread in the Anglo-Saxon-speaking countries especially thanks to the British novelist Samuel Butler, who first translated Hering’s work in the book *Unconscious Memory* (1880). The idea that

both memory and biological inheritance were based on the persistence of vibrations accentuated the role of mental factors in evolution and was often used to counteract the Darwinian view of heredity and evolution (Ceccarelli 2018). The American neo-Lamarckians Alpheus Hyatt (1838–1902) and Edward Drinker Cope (1840–1897) strongly opposed Darwinian pangenesis, as it was quite impossible for them to imagine that the gemmules could find their exact place in the growing embryo. The transmission of “a mode of motion” organized in a central nervous system was considered less inconceivable than any discrete model of inheritance (Cope 1896).

The work of the German cytologist August Weismann (1834–1914) represented a major breakthrough in the debate. Since early 1885, Weismann had maintained that the germplasm was unaffected by the activity of development and isolated from indirect environmental influences. In 1888, he affirmed that somatic modifications do not affect the germ line after he demonstrated that the descendants of mice whose tails had been detached continued to grow tails. This was the start of the so-called neo-Darwinian school, since sexual reproduction (*amphimixis*) became the only source of variability for natural selection to act upon. Even though many naturalists accused Weismann of having mistaken accidental modifications for acquired characters, his conclusions were generally considered the fatal blow to the inheritance of the acquired characters and habits. Furthermore, Weismann’s experimental work questioned the very idea of the interchangeability between biological and social inheritance, which, in turn, favored a first fundamental separation between biological heredity and cultural learning in social sciences (Ceccarelli 2018).

Experimental Biology and the Discontinuous View of Inheritance

Between the nineteenth and the twentieth centuries, the debate on inheritance underwent significant technical and methodological changes. Innovative cytological studies expanded the

knowledge of the cell's architecture. During the 1870s, the Swiss chemist Friedrich Miescher (1844–1895) and the biochemist Albrecht Kossel (1853–1927) identified nucleic acids. In 1882, Walther Flemming (1843–1905) coined the term “mitosis” to describe the longitudinal division of those nuclear corpuscles that, in 1888, the German anatomist Wilhelm Waldeyer-Hartz (1836–1921) first termed “chromosomes” (Wall 2015).

It was the experimental studies on plants' hybridization that provided the ground for the quantitative description of hereditary processes. Gregor Mendel (1822–1884) conducted his well-known crossing experiments with peas (*Pisum sativum*) between 1856 and 1863. His results were published in the paper *Versuche über Pflanzenhybriden* (1866), where he exposed his main generalizations. By analyzing an amount of about 28,000 plants, Mendel observed that the hybrids, instead of presenting a fusion of the parental characters, showed specific morphological patterns. He assumed these characters were linked to distinct hereditary factors which come in pairs, one from each parent. The combination between the variants (*alleles*) of these factors determined the character of the offspring. Organisms with two identical alleles were *homozygous*, while those with different alleles were *heterozygous*. However, the physical appearance of the hybrids showed that some variants prevailed over others. For instance, in heterozygous plants for pea seed color (*yellow/green*), the yellow variant prevailed over the green one. In spite of this, the unexpressed variant remained unaltered and thus transmissible to the offspring. Although the separation and recombination of factors occurred randomly, the expression of the hereditary constitution of the plants revealed proportional relationships that Mendel described in terms of dominant-recessive factors.

The idea that the organisms carried unexpressed hereditary discrete factors, as well as the broader attitude towards a quantitative description of inheritance, determined one of the deepest breaks in nineteenth-century life sciences. It has been suggested that the very dichotomy between “blending” and “non-blending”

inheritance is a product of the post-Mendelian biology (Müller-Wille and Rheinberger 2012). Mendel's work provided an explanation to many mysteries of inheritance (Watson 2003), although his conclusions were scarcely noticed by his contemporaries, at least until 1900.

Even before the rediscovery of Mendel's researches by Hugo de Vries (1848–1935), Carl Correns (1884–1933), and Erich von Tschermak (1871–1962), several scientists had however developed a discontinuous view of inheritance. In *Hereditary Genius* (1869) and *Natural Inheritance* (1889), Darwin's cousin Francis Galton (1822–1911) critically assessed the Darwinian view of inheritable variations. According to his studies on statistical correlation and regression, minimal variations tended to regress to the average value. It followed that the only evolutionary-relevant variations had to be discrete alterations (*sports*) at the germinal level. In *Materials for the Study of Variation* (1894), William Bateson advanced the hypothesis that the discontinuity among species mirrored discrete variations.

In 1902, the American physician Walter Sutton (1877–1916) observed that, in the body cells, chromosomes occurred in pairs, while in germ cells, they appeared in single structure. This architecture well-matched Mendel's description of alleles' behavior. In parallel with the German cytologist Theodor Boveri (1862–1915), Sutton laid the foundation to the chromosome theory of heredity, which turned the Mendelian factors into material and localizable objects. In *The Genotype Conception of Heredity* (1911), W. L. Johannsen coined the term “gene” to designate the Mendelian “unit factors.” He further proposed the well-known dichotomy between “genotype” and “phenotype,” which is widespread in the science of genetics throughout the twentieth century.

The endorsement of Mendelism was however not undisputed. During the 1910s, Thomas Hunt Morgan maintained a skeptical view as to the epistemological significance of Mendelism. Indeed, Morgan initially saw in Mendelism a methodological fallacy common to many nineteenth-century studies of inheritance, i.e., postulating the existence of unverified

processes and physical units. By assuming the existence of factors responsible for hereditary processes, Mendelism was still implying an unknown material basis (Morgan 1909, p. 365). About a year later, Morgan became one of the foremost proponents of Mendelism thanks to his now famous experiments on *Drosophila melanogaster* he had carried out at Columbia University between 1907 and 1910. Not only did the experiments confirm Sutton-Boveri's chromosomal theory, they also showed that the phenotypic expression of certain characters (the white-eye recessive trait in flies) was linked to the chromosomal spot of Mendelian factors and, in particular, to sex.

The study of phenotypes in Mendelian terms did not just involve body characters. As a matter of fact, in the early twentieth century, eugenicists used to trace back individuals' behaviors and personal attitudes to the action of single genes (Watson 2003). As a result of the Mendelian revolution and the Weismannian turn in the 1880s, nineteenth-century environmental determinism often turned into genetic determinism.

The Century of the Gene

In the 1940s, the study of biological inheritance did benefit from the groundbreaking researches on organic molecules. The achievements in X-ray crystallography help scientists determine the molecular structure of organic macromolecules, thus revolutionizing organic chemistry (Mitchinson 2014). Even though the analysis of the conformation, function, and interaction among organic substances was not originally aimed at scrutinizing hereditary phenomena, it laid the foundations for what has been later called the "molecularization" of genetics (Müller-Wille and Rheinberger 2012).

Between 1940 and 1952, scientists identified the deoxyribonucleic acid (DNA) as the material basis of genetic information. In 1944, Oswald Avery (1877–1955), Maclyn McCarty (1911–2005), and Colin MacLeod (1909–1972) of the New York Rockefeller Institute discovered that the DNA could transmute

the characteristics of the cell while studying the *Streptococcus pneumoniae*. In 1952, Alfred Hershey (1908–1997) and Martha Chase (1927–2003) of the Cold Spring Harbor Laboratory confirmed that DNA was the transforming factor as well as the very material basis of heredity. It was only a year later that D. Watson (1928) and F. C. Crick (1916–2004) famously proposed the double-helix model to describe the structure DNA macromolecules.

Watson and Crick showed that each DNA chain was composed of sequences of nucleotides (*adenine*, *cytosine*, *guanine*, and *thymine*) that coded for molecules with specific functions. While molecular biology provided the technologies and operational methods for the understanding of the material basis of heredity, modern communication technologies and cybernetics allowed scientists to shape the informational conception of biological inheritance. As a matter of fact, the nineteenth-century energetic conception of inheritance came to be replaced by expressions such as "biological information," "genetic program," "transcription," and "genetic code" (Fox Keller 1995; Maynard Smith 2000; Müller-Wille and Rheinberger 2012). As early as 1944, Erwin Schrödinger's essay *What is Life?* had introduced the notion of "hereditary code" to designate the information enclosed in the chromosomes. As Watson affirmed (2003), many of the pioneers in the field of molecular biology assumed Schrödinger's idea that the transmission of characters followed definite set of instructions.

Between the 1950s and the 1960s, such instructions had their quintessential reification in the so-called central dogma of molecular biology, the idea that molecular information could only flow from DNA to proteins via messenger RNA (mRNA). The first phase of the process is that of *transcription*, where DNA segments are replicated into mRNA. During the second phase, called *translation*, the copied information is conveyed in the ribosomes and finally translated in proteins.

This one-way conceptualization of biological information did play a major rule in reinforcing the neo-Darwinian view of germ line inheritance, creating "an impression of straight-line progress

in genetics and from Mendel to Weismann to Morgan to [Watson] and Crick's decoding of DNA to the Human Genome project to gene therapy" (Depew 2017, p. 75).

Between the 1960s and the 1970s, the analysis of genetic sequences in relation to the genetic variants involved in hereditary diseases gave rise to the "genomic revolution" (AA.VV. 2006). The use of enzymes and plasmids to modify and manipulate the genetic material in the cells (Morange 1994) made a methodological switch that redefined the institutional, disciplinary, and epistemic status of genetics. In this regard, the milestone was reached in 2001 and 2003 with the Human Genome Project and the determination of euchromatic human genome.

Behind the applicative side of these researches, new theoretically significant evidence was brought to the attention of scientists. The sequencing of the human genome did raise questions about the actual functioning of the genome. Scientists discovered that it required "more than just knowledge of the order of the base pairs" to cure human disease and started to focus their attention to those regions of the genome "devoid of traditional protein-encoding genes" (Chial 2008) that play a major regulative role in gene expression during the individual development.

At the same time, new experimental evidence questioned the "central dogma." As early as 1970, Howard Temin (1934–1994) and David Baltimore discovered a viral polymerase that could transcribe RNA molecules into DNA molecules. The enzyme that appeared to break the central dogma was named "reverse transcriptase." Further anomalies were brought to light in the studies of development and evolution. Between the 1940s and the 1950s, the British embryologist Conrad Hal Waddington (1905–1975) and the Russian zoologist Ivan Schmalhausen (1884–1963) had independently showed that developmental and genetic variations could lead to phenotypic plasticity and genetic canalization. In *Canalization of Development and the Inheritance of Acquired Characters* (1942) and *Genetic Assimilation of an Acquired Character* (1953), Waddington argued that environmentally

induced adaptations could become inherited characters without implying the Lamarckian mechanism of inheritance. Waddington called such process "genetic assimilation" and explained it as the outcome of the plastic abilities grounded in organisms' genetic potentialities. Through the perturbation of development, Waddington argued, the individual ontogeny escapes its standard pathway (*decanalization*) which, in turn, may reveal cryptic genetic variations.

Waddington termed the branch of biology "epigenetics," whose aim was that of studying the causal interactions between genes and their products which bring the phenotype into being (Waddington 1942). However, it took decades for evolutionary biologists and geneticists to fully grasp the operational and theoretical potentialities of Waddington's proposal. For decades, biologists found DNA, the genetic code, transcription, and translation "far more exciting" (Lamb 2009, p. 118).

Inheritance in the Post-Genomic Era

There is enough agreement that contemporary biology has undergone a "holistic turn" by now. Terms such as "post-genomics" and "epigenetics" have come to the fore in the last three decades leading to a systemic view of hereditary processes and organisms' complex development (Müller-Wille and Rheinberger 2012). In post-genomics, phenotypes are no longer considered the mere expression of genetic information but rather as the manifestation of "systems of development," which include factors that have been traditionally considered as environmental (Griffiths and Stotz 2006). The genome is more frequently conceived as a broad and hierarchical regulatory network that interacts with external inputs (Dupré 2012).

Along the lines of Waddington's research agenda, the Evo-Devo studies are now proposing a new synthesis among molecular biology, embryology, genetics, and epigenetic inheritance. Since the early 1990s, the phenomenon of transgenerational epigenetic inheritance has been deeply reconsidered by molecular biologists.

Scientists have surveyed several examples of inheritable gene alteration and deactivation (*silencing*) in response to environmental stimuli, with specific regard to the process of DNA methylation by which the genes' expression is modified. There is increasingly evidence that information is also conveyed through non-DNA portions of chromosomes, self-sustaining metabolic loops, chromatin-marking systems, and small RNA molecules able to suppress gene activity (Jablonka and Lamb 2015).

All this has unsurprisingly stimulated a historical and epistemological reflection, which largely deals with the uses of terms such as “epigenetics,” “epigenesis,” “epigenetic inheritance,” and even “Lamarckism.” To designate nongenetic inheritance, scientists have sometimes used the more general term “epigenetics,” i.e., the study of the processes that underlie developmental plasticity and canalization (Jablonka 2009). Moreover, the very term “epigenetic inheritance” has a double meaning:

Epigenetic inheritance in the narrow sense refers to the cellular epigenetic inheritance [...] in which the unit of transmission is the cell. Epigenetic inheritance in the broad sense includes body-to-body (or soma-to-soma) information transfer between generations of individuals. This can take place through developmental interactions between mother and offspring, through social learning, through symbolic communication, or through the transmission of symbionts and pieces of DNA between individuals. (ivi, p. 151)

In some cases, the narratives of the epigenetic turn have revived the interest in Lamarckism. Since epigenetic inheritance can lead to a form of soft inheritance, scholars have advanced the hypothesis of a revival of Lamarckian issues. This has stimulated further historical discussions of the conceptual parallelism between epigenetic inheritance and the classic notion of inheritance of acquired characteristics (Loison 2018).

Conclusions

The history of biological inheritance has been characterized by various discussions. Concepts from other areas have played an operative role in

the shaping of the various theories of inheritances throughout the centuries. A thorough analysis of the subject easily reveals how discussions of inheritance have long referred to a wide and complex phenomenology (genetic and epigenetic inheritance, cultural transmission, social learning) whose inquiry has undergone further specialization between the nineteenth and the twentieth centuries.

Beyond a seemingly constant alternation between reductionists and holistic stances, recent developments in the field of post-genomics seem to challenge the classic accounts of genetic determinism and hereditarianism, according to which the organisms' phenotypic as well as behavioral characteristics would be reducible to the genotype alone.

Definition

Many species have faced sperm competition (when sperm from two or more males compete to fertilize an egg in a female’s reproductive tract) in their ancestral past to varying degrees. In the history of human evolution, the common mating system of social monogamy led to decreased levels of sperm competition relative to some other primates; however, it was not completely absent. Evidence of this history of sperm competition is seen in both men and women in terms of their genetic makeup, anatomy, and evolved mating psychology.

Introduction

In humans, there is evidence that they repeatedly faced sperm competition in their ancestral past. That is, women mated with two or more men in a sufficiently brief window of time to allow sperm from more than one man into their reproductive tract that subsequently would compete to fertilize ova (Parker 1970). Because the most common mating system in humans is social monogamy (Brown et al. 2009), sperm competition can have a large impact on men's reproductive success through their regular partner's engagement in extra-pair mating and subsequently producing offspring sired by another male. This scenario leads to men unwittingly investing in genetically unrelated children (Trivers 1972).

This situation does occur in contemporary human societies, with an average rate of 3.1% of children having a different biological father than the one socially regarded as their father (Voracek et al. 2008). However, this rate sharply increases with degree of paternity uncertainty as men who reported having low confidence in paternity of their children experience a nonpaternity rate of 29.8%, while those with high paternity confidence experience only a 1.7% nonpaternity rate (Anderson 2006). Additionally, women report "double mating" or mating with more than one male within a 5-day span at least once in their lifetimes at a rate of 17.5% (Baker and Bellis 1993a). As such, men currently exhibit both physiological and psychological adaptations to sperm competition in order to avoid cuckoldry (and the subsequent reproductive cost of raising unrelated children) and women exhibit adaptations to manipulate the outcome of sperm competition in their favor (Shackelford et al. 2015). These adaptations would not have arisen without the presence of sperm competition in humans' evolutionary past. The following presents evidence of this history of sperm competition in humans.

Evidence in Men

In some primate species, females commonly mate with multiple males (polyandry) and in other

species they mainly mate with one male (monandry; Harcourt et al. 1995). In species practicing polyandry, the risk of sperm competition is greater, and the male genitalia of these species evolved to adapt to this greater risk. Specifically, more sperm is needed to be produced to outcompete that of rivals, and polyandrous species have larger testes capable of producing enough sperm to meet the demands of sperm competition (Harcourt et al. 1981; Short 1979). Relative testis size and the number of sperm per ejaculate correlate positively with the degree of polyandry; for example, monandrous gorillas have relatively small testes, while highly polyandrous chimpanzees have rather large testes in proportion to body size (Harcourt et al. 1995). Humans have testes that are intermediate in size (in proportion to body size) compared to both the gorilla and the chimpanzee, which signals an intermediate level of sperm competition risk in humans (Smith 1984).

Similarly, the length and shape of the human penis has been noted as evidence of a history of sperm competition. The length is longer than that of any other ape (Short 1979) which is argued to give men an advantage in sperm competition. Specifically, the long penis can deposit sperm close to the cervix which gives the sperm an advantage in the race toward the egg as they would have a shorter distance to travel (Baker and Bellis 1995; Smith 1984). In terms of shape, it has been proposed that the coronal ridge of the penis is designed to displace rival semen that was previously deposited in a woman's reproductive tract (Baker and Bellis 1995). Empirical evidence to support this hypothesis was provided by Gallup et al. 2003, who used artificial genitals to conclude that phalluses with a coronal ridge displaced up to 90% of simulated semen while phalluses lacking a coronal ridge only displaced 35.3%. In further detail, this displacement seemed to function by the coronal ridge allowing semen to flow back and collect under it; however, this only was able to occur when at least 75% of the length of the penis was inserted into the simulated vagina (suggesting again that length is important for sperm competition). Finally, the refractory period that men experience after an ejaculation (period in

which an erection cannot be achieved) can also be argued as evidence of the semen displacing ability of the human penis, as it would be reproductively costly for a man to displace his own sperm (Gallup and Burch 2004).

At the genetic level, there also exists evidence of some history of sperm competition in humans. Upon examination of protamine genes (genes involved in the production of functional spermatozoa), they seem to be somewhat similar to those found in polygamous rodents as well as being thought of as comparable to the more polygamous chimpanzee in primate terms (Martin-Coello et al. 2009; Wyckoff et al. 2000). Other research looking at genes that encode seminal fluid proteins suggest a more moderate history of sperm competition. Specifically, in many nonhuman species (including other primates such as the gorilla and chimpanzee), proteins in seminal fluid function to form a “mating plug” within the female reproductive tract as a means of blocking sperm from rival males in subsequent matings (Lievers and Simmons 2014), and the rate of evolution of a certain gene involved in the production of the proteins necessary to form the mating plug is positively correlated with the level of sperm competition within a species (Clark and Swanson 2005). Among primates, the rate of evolution of this gene is only moderate in humans compared to the highly promiscuous chimpanzee (Dorus et al. 2004).

Beyond anatomical evidence, men try to boost their paternity confidence of offspring that may result from sexual relations with a given woman and therefore have evolved preferences for mates that will provide them with the least amount of sperm competition, even in short-term contexts (Shackelford et al. 2004). Consistent with these preferences, men are most likely to report a desire to pursue a short-term relationship with a woman who is neither married nor involved in casual sexual relationships as this situation presents no risk of sperm competition; men were least interested in a short-term relationship with a married woman, as frequent inseminations from a husband present a high sperm competition risk (Shackelford et al. 2004).

Another part of men’s mating psychology related to the threat of sperm competition is the strength of male sexual jealousy. Not only do men attempt to choose mates that pose a low sperm competition risk, once finding a low-risk partner they try to further minimize the opportunities for her to engage in extra-pair copulations with other men, and this is often motivated by jealousy (Shackelford et al. 2015). Men react with stronger jealousy to just imagining their regular partner engaging in sexual intercourse with someone else compared to women (Buss et al. 1992). This jealousy and its use as a mate retention tactic tend to keep men’s regular partners away from potential rivals in order to avoid the consequences that can be attached to that jealousy. In the most extreme of cases, male sexual jealousy can lead to men murdering their partners; this is also the leading motive for men to kill their partners (Buss 2006). Such strong reactions to potential extra-pair copulation are evidence of sperm competition as a recurring theme among humans’ evolutionary past.

Evidence in Women

While men’s adaptations to sperm competition are designed to avoid cuckoldry, women’s adaptations to sperm competition are designed to ensure its outcome serves their best reproductive interests. These adaptations concern both pre-copulatory and postcopulatory female mate choice (Shackelford et al. 2015). In precopulatory mate choice, women have the most reproductive success from forming a long-term relationship with a man who is willing to invest in her and her children to increase the chances of offspring survival (Trivers 1972). However, the type of mate that a woman can secure as a long-term investing mate and the type of mate that can offer the most in terms of good genes that could be passed to her offspring may be different from one another (Gangestad et al. 2015). Specifically, men with traits signaling “good genes” such as muscularity, masculinity (in the body, face and voice), symmetry, and social dominance typically have high testosterone levels and subsequently are

less likely to display a willingness to be faithful and invest in one woman (Pollet et al. 2011). Therefore, it is adaptive for women to strive to obtain both paternal investment and good genes to maximize reproductive success by having a long-term mate and engaging in extra-pair copulations with men of superior genetic quality when conception risk is the highest (Gangestad et al. 2015).

This speculation has been supported by research finding that while women's sexual attraction to their regular partner remains unchanged across the ovulatory cycle, their sexual attraction to and likelihood of sexual fantasizing about men other than their partner is more likely to occur during the fertile window of the ovulatory cycle (Pillsworth and Haselton 2006). This also translates into behavior as women are more likely to engage in extra-pair sex when conception risk is high, especially when their regular partner is not of relatively high genetic value (Garver-Apgar et al. 2006). Not only do women engage in extra-pair mating during high fertility, but they also strategically schedule copulations with their regular partner to manipulate sperm competition outcomes as well. When women have recently engaged in an extra-pair mating, they tend to delay copulation with their regular partner in order to give the rival male an advantage in sperm competition (Gallup et al. 2006).

In postcopulatory mate choice, female orgasm seems to be the driving force in sperm competition outcomes. It has been speculated that the female orgasm is an adaptation for selective sperm retention, as its occurrence causes uterine contractions that facilitate the retention and transfer of a greater number of sperm into the reproductive tract (Baker and Bellis 1993b, 1995). Because women want the best quality genes for their offspring, the finding that women mated to more symmetrical men (a sign of genetic quality) have more copulatory orgasms than women mated to less symmetrical men (Thornhill et al. 1995) might be support for the argument of female orgasm being an adaptation. In addition to the presence of female orgasm during copulation for sperm retention, the timing of such orgasms may be just as (if not more) important for this purpose (Smith 1984). According to research by Baker and Bellis

(1993b), the optimal timing for female coital orgasms for greater sperm retention is between 1 min before and 45 mins after male ejaculation. This was concluded after examining seminal and vaginal fluid that was ejected from the vagina after copulation (known as flowback), and less sperm was ejected when female orgasm occurred during this time frame. Furthermore, for women with extra-pair partners, they report having more of these high-retention orgasms within this time frame with the extra-pair partners compared to their regular partners (Baker and Bellis 1993b). This is also indicative that women may promote sperm competition and bias the outcome in favor of an extra-pair partner that likely is of greater genetic quality.

Related to female orgasm as an adaptation concerning sperm competition outcomes is men's interest in ensuring their partner achieves orgasm. One study found that men who spent more than 50% of time away from their partner since the couple's last copulation reported a greater interest in their partner's copulatory orgasm than men who spent less than 50% of time away from their partner (McKibbin et al. 2010). More specifically, sperm competition risk (as measured by percentage of time spent away from partner) moderated the effect of relationship satisfaction and investment on interest in partner orgasm, such that men who reported a greater sperm competition risk and greater relationship satisfaction and investment were particularly likely to report an interest in and attentiveness to their partner's copulatory orgasm. The association between relationship satisfaction and investment and interest in partner orgasm was not significant for men who reported lesser sperm competition risk, suggesting this interest is motivated by wanting to get an advantage in potential sperm competition.

Conclusion

Humans have faced a significant degree of sperm competition in their evolutionary history. Between the highly promiscuous chimpanzee and the monandrous gorilla, the level of sperm

competition in human mating systems is moderate, but this moderate amount is enough to warrant the development of adaptations in response to sperm competition in both men and women. For men, they have evolved adaptations to both avoid sperm competition and to also have an advantage in winning such competition on the occasions in which it does occur. Their genitalia evolved to generate enough sperm to be competitive in a lottery or scramble scenario and also to displace rival sperm that may already be present in a woman's reproductive tract. Genetic indicators of moderate sperm competition exist in men as well. Psychologically speaking, men have evolved preferences to avoid choosing a long-term mate that would be of high sperm competition risk and, once in an exclusive sexual relationship, men have evolved strong sexual jealousy to deter their partners from engaging in extra-pair copulations.

In women, sperm competition adaptations function to manipulate its outcome in their favor. In terms of reproductive success, it would be optimal for women to have a regular partner from which they can secure paternal investment and also strategically engage in extra-pair copulations during periods of high conception risk to secure genes superior to those that can be obtained from the long-term partner. To aid in utilizing this strategy, women's sexual preferences change throughout the ovulatory cycle such that they are more attracted to men other than their regular partner during times of high fertility. Women also can manipulate the outcome of sperm competition in the incidence of "double mating" by strategically having orgasms during copulation with the partner that is deemed genetically superior to retain more of his sperm. For being a moderate selection pressure on human mating dynamics, sperm competition has had considerable influence on the evolution of human sexuality.

Individuals who are perceived as the most attractive individuals in society who work in film and television.

Introduction

Hollywood actors have the ability to transform their stage into another dimension for their

audience. With this ability, many people covet these Hollywood actors and their lifestyle that comes with the territory. However, being a successful Hollywood actor depends largely on the physical attractiveness of their appearance to the population. Each gender of Hollywood actors conforms to the common perception of what makes an individual attractive. By being able to abide by these perceptions of attractiveness, many Hollywood actors manage to find roles that remain within their levels of attractiveness and portray a character that their audience will find appealing. With the pressure of abiding by the common belief that Hollywood actors must remain attractive in order to stay successful, some Hollywood actors can be seen as being more prone to anger. Although Hollywood actors have the stress with remaining physically attractive to their audience to earn more work in their trade, some would argue that the stress is not what makes them more prone to anger. Rather, Hollywood actors, because they are attractive, are more prone to anger because of their appearance not because of their trade.

Attractiveness and Hollywood Actors

The common belief that in order to be a successful actor in Hollywood comes from the perception of attractiveness of the individual. Thus, each gender of Hollywood actors must adhere to the common perception of what makes each gender attractive to others. For example, females are perceived as attractive when they have lower body weight, whereas males are perceived as attractive when they have a higher body weight (McCreary and Sadava 2001). Female Hollywood actors follow the common belief that having a smaller body structure will make them more appealing to their audience. As a result, females are more likely to diet and are more likely to use unsafe weight-loss strategies to remain physically attractive (Connor-Greene 1988). In addition to a lightweight body structure, females are perceived as more attractive when they maintain an element of youth to their physical appearance. Females are considered more attractive, and thus a more successful Hollywood actress, when they reduce the effect of aging in

film roles (Lincoln and Allen 2004). Age changes the facial structure of females that make them dissatisfied with their physical appearance. When females age, their lips, eyes, and cheeks are making structural changes to their facial structure that distance themselves further from cultural beauty standards set by Hollywood (Franzoi and Koehler 1998). So with both youth and a lightweight body structure, these females have a higher perception of attractiveness in Hollywood. As a result, those females who are considered attractive are portrayed more favorably in film and television than characters who are considered unattractive (Smith et al. 1999). Females use both age and body structure to influence their perception of attractiveness, and Hollywood actresses that can abide by the cultural standards of beauty are considered more successful in their trade.

Like females, males also adhere to cultural standards of beauty to obtain success in Hollywood as an actor. Unlike females, males' body structure is to have a higher weight because it perceives the males as having muscle and strength. With having a higher body weight, males can distort the perception of their body to have others perceive them as attractive. For instance, body structure can perceive certain facial characteristics, specifically a prominent jaw line, to associate these facial characteristics with masculinity and strength (Windhager et al. 2011). Males who are considered muscular have more success in Hollywood as an action star and remain within that field of acting for several roles. Males view these Hollywood actors as successful because it remains their ideal body structure that cultural standards have promoted (Leit et al. 2002). In addition, younger men who perceive a larger body with more muscle mass and less body fat is what both males and females would find attractive (Lynch and Zellner 1999). Therefore, similar to females, emphasis on body structure influences the perceptions of what males consider to be attractive.

Attractiveness and Anger

Anger is an emotion that every individual expresses in their lifetime and has been examined to determine who are more likely to be anger-

prone. Hollywood actors and actresses consistently argue that anger is a response to the stress and pressure of their career. However, research shows that the pressure and stress of working in Hollywood may not be the reason why some Hollywood actors are anger-prone. Children who have been reported as some of the most aggressive students toward teachers have also been perceived as being some of the most physically attractive children (Hawley et al. 2007). Thus, the argument that the stressful work environment creates the response of anger does not sufficiently address that more physically attractive individuals tend to have more aggression and anger in their lives. Females' perception of attractiveness is related to their emotion of anger, and males are more prone to anger when they view themselves as physically attractive (Sell et al. 2009). Accordingly, being perceived as more physically attractive makes an individual more prone to anger regardless of their career choice. Therefore, Hollywood actors and actresses, because they are perceived as some of the most physically attractive individuals within the population, will be more prone to anger than others.

Research has shown that individuals who are physically attractive are more prone to anger. In addition, individuals who are considered some of the most successful actors and actresses in Hollywood have been considered some of the most physically attractive individuals. As a result, media consistently reports on incidences of anger, aggression, and violence of Hollywood actors and actresses. In 2014, a Hollywood actress physically fought with her brother-in-law in a hotel elevator. In another incident in 1992, a different successful Hollywood actress was arrested for battery after being involved with an altercation with another female. However, Hollywood actors also have a lower threshold for anger and aggression to handle disputes. Over the years, several Hollywood actors have been involved with physical disputes with paparazzi in the public streets. In one incident in 2013, a successful Hollywood actor was engaged in a shoving match with a member of the paparazzi. Hollywood does have several different pressures placed on actors and actresses, but research helps understand that its more of the

belief that attractive individuals have a lower threshold to anger and aggression in handling disputes.

Conclusion

Hollywood actors and actresses are considered as the most attractive individuals in society. By adhering to the cultural beauty standards, certain individuals are able to obtain a successful career in Hollywood, while others are considered not as successful. Females are perceived as attractive, and therefore more successful, when they maintain a lower body weight and youth. Aging is believed to make Hollywood actresses less employable and less appealing in Hollywood making them less popular in media. However, males are perceived as attractive in Hollywood when they have a higher body weight compared to females because it perceives them as muscular and having strength. While Hollywood actors and actresses are some of the most attractive individuals in the population, individuals who are perceived as more attractive are more prone to anger and aggression. Several incidences that have been seen in the media involving Hollywood actors show how attractiveness leads to a higher likelihood of anger.

Holmes and Sherman (1982) on Ground Squirrels

Definition

Phenotype matching refers to the ability to detect genetic relatedness based on phenotypic cues of the self or close kin.

Introduction

In laboratory studies it was found that Belding's ground squirrels (*Spermophilus beldingi*) are able to recognize kin with which they did not share natal burrows. Related female individuals, even if they were unfamiliar to each other, were less agonistic than unrelated individuals. Field studies also showed that littermate full-sisters treat each other differently than maternal half-sisters. This suggests that both rearing environment and relatedness have crucial contribution to nepotistic behavior in ground squirrels. Similar results with other rodent species imply that learning and recognition of cues of probable genetic relatedness, known as phenotype matching, might be a mechanism which influences social interactions.

Mechanisms of Kin Recognition

Hamilton's inclusive fitness theory suggests that it would be advantageous for individuals to show a biased behavior for conspecifics who are genetically more closely related. Preference for kin could help optimize prosocial behavior within the group (nepotism) and mate choice decisions (inbreeding avoidance, optimal outbreeding, see Bateson 1983). However, for nonsedentary species, as dispersal from the native group is common, differentiating between kin and nonkin could be a challenge. At least four possible mechanisms of kin recognition were outlined (Mateo 2003).

First, *spatial cues* (i.e., co-residence) can inform individuals about relatedness.

Second, *early association* is a somewhat better heuristic for the estimation of kinship. For species which disperse after the juvenile period and, therefore, may easily find themselves in the proximity of nonrelated conspecifics, co-residence is an uncertain cue of genetic closeness.

Third, as a theoretical possibility, it has been proposed that *recognition alleles* could serve the recognition of related individuals. This allele should be expressed phenotypically,

recognized by others and it is expected to increase the likelihood of preferential treatment of the individuals with that cue.

Fourth, if there is a correlation between the similarity of phenotypic traits and the amount of shared genes, *phenotype matching* can provide individuals with the necessary information about relatedness. During the juvenile period they can learn either the cues (e.g., odors) of their littermates and other co-residing conspecifics (other-referent phenotype matching), or that of their own (self-referent phenotype matching), and later use these as a recognition template to assess genetic relatedness to unfamiliar individuals.

Ground Squirrels as Model Animals

Holmes and Sherman (1982) used Belding's ground squirrels (*Spermophilus beldingi*) and Arctic ground squirrels (*S. parryi*) as model animals to test whether phenotype matching is used for kin recognition in these species. They cross-fostered preweaned pups in a laboratory environment and tested the behavior of related and familiar individuals and related and unfamiliar individuals in pairs. It turned out that ground squirrels which were reared together treat each other as siblings, that is, they are not more agonistic than sibling pairs. Besides, female siblings reared apart showed less aggressiveness than unrelated female pairs. Field observations of Belding's ground squirrels revealed also females' ability to discriminate between full-sisters and maternal half-sisters, despite they shared the natal burrow with both sibling types. They are more cooperative and less agonistic with full-sisters than with half-sisters – an impressive demonstration of the inclusive fitness theory. Hence, it was suggested, shared environment shape prosocial behavior and so does genetic relatedness.

In subsequent experiments, the role of phenotype matching in kin recognition was studied further. It was shown that females of *S. beldingi* treat paternal half-sisters differently than unrelated females (Holmes 1986a). In this case, as these

siblings were reared apart, familiarity could not contribute to the biased behavior. When female ground squirrels were cross-fostered and reared in a mixed group of related and unrelated littermates, paired arena tests confirmed that both shared natal environment and relatedness affects the frequency of agonistic acts (Holmes 1986b). On the one hand, when females encountered unrelated females, the level of aggression was modest. Note that due to cross-fostering they were mutually the sisters of each other's littermates. This shows that exposure to a certain phenotype in the natal burrow is used later as a template to which other individuals are compared (Holmes 1984). In this case, information about phenotypic cues of nonrelated littermates is used to recognize kin of that littermates (other-referent phenotype matching). On the other hand, unfamiliar sisters are recognized and preferred as well, even in case the pup does not share its natal environment with any relatives, preventing the use of phenotypic cues other than her own (self-referent phenotype matching).

Conclusion

The ability to recognize kin, and to prefer them over conspecifics who are genetically not related, has been observed in many taxa, including insects and mammals. It has been suggested that this bias was selected for during evolution and might be best explained by the theory of inclusive fitness. Several mechanisms have been put forward to account for kin recognition, most notably *phenotype matching*. In their influential paper, Holmes and Sherman (1982) provided evidence that ground squirrel pups (*Spermophilus sp.*) learn phenotypic cues of both their littermates and their own, to which unfamiliar individuals are compared at later encounters. Though theoretically both sexes might use this ability the discriminate between conspecifics with different degrees of relatedness, biased behavior is limited to female–female interactions. This suggests that kin-recognition is used in these rodent species as a means of nepotism, rather than that of optimal mate choice.

Homicide Adaptation Theory

Definition

Evolved psychological mechanisms to facilitate killing other humans.

Introduction

Violence has been a recurrent and persistent occurrence throughout the expanse of human history (Daly and Wilson 1988; Pinker 2011). An evolutionary psychological perspective proposes that violence is inherently and inextricably entrenched in human psychology. Accordingly, this perspective suggests that over deep evolutionary history, humans have evolved adaptations for aggressive behavior as means of solving a variety of adaptive problems (Buss and Shackelford 1997). Thus, the capacity for violence disposed by modern humans may be the result of selection favoring aggressive tendencies. In particular, aggressive behavior may have emerged as a pattern of solutions to the many problems presented by group living.

Buss and Shackelford (1997) proposed seven domains for which aggression may serve effective means: (1) co-opting resources from others, such as fertile land, water access, or tools; (2) defending against an attack from conspecifics, which can result from others employing the previous strategy and poses a serious threat to the survival of the victim; (3) inflicting costs on intrasexual rivals, typically within the context of intrasexual competition for mates; (4) negotiating status and power hierarchies in relevant contexts; (5) deterring rivals from future aggression, which can include creating and maintaining a reputation for aggression; (6) deterring mates from sexual infidelity as a means to ensure paternity or paternal investment; and (7) reducing resources expended on unrelated children by means of infanticide. Two of these domains in particular – inflicting costs on intrasexual rivals and reducing resources expended on unrelated children – often include the killing of another human.

Homicide as an Adaptation

In every culture studied, people have been documented killing other people. Although many species kill members of their own species via competition, the sophistication of human killing is observed in only one other species – chimpanzees (*Pan troglodytes*; e.g., Mitani et al. 2010), the phylogenetically closest living relative to humans. Duntley and Buss (2005, 2011) proposed *homicide adaptation theory* to explain why people kill other people. Homicide adaptation theory states that humans have evolved adaptations to facilitate killing in specific, and evolutionarily-recurrent, contexts for which the benefits of killing outweigh the costs. The majority of killings perpetrated by humans are believed to be the product of evolved psychological mechanisms designed by natural selection to ensure the death of conspecifics.

Homicide has not been perpetrated indiscriminately over human evolutionary history. Rather, killing of conspecifics occurs in highly specific contexts that have posed recurrent adaptive problems over human evolutionary history. Duntley and Buss (2005, 2011) propose specific contexts for which homicide may have been ancestrally advantageous, including: (1) preventing the exploitation of self, kin, mates, or coalitional allies from conspecifics; (2) reputation management to avoid appearing exploitable; (3) protecting resources; (4) eliminating individuals who utilize resources, but who provide no fitness benefits to the aggressor (e.g., step-children); (5) eliminating genetically related individuals who pose a significant fitness cost to the perpetrator; and (6) gaining access to mates. Homicide adaptations could therefore have evolved if, on average, homicide increased the fitness benefits of the perpetrators, relative to the fitness costs.

Homicide adaptation theory does not propose that homicide is the preferred strategy as a solution to any of the above adaptive problems. In most circumstances, the costs of homicide are far too high to make it a viable strategy. Instead, according to homicide adaptation theory, homicidal behavior may have been the best solution for some adaptive problems in some circumstances.

Converging lines of evidence provide support homicide adaptation theory as an explanation for the ubiquity of homicide in human history and cultures (Duntley and Buss 2005, 2011).

Homicide adaptation theory proposes that selection has shaped distinct homicide adaptations for men and women (Duntley and Buss 2005, 2011). More generally, men are significantly more likely to engage in violent and potentially lethal behavior than are women. Pioneering work by Daly and Wilson (1988) demonstrated that the proportion of male-male homicides substantially exceeds the proportion of female-female homicides in every culture studied. National statistics reported by Daly and Wilson (1988) are corroborated by a network of evidence demonstrating physical, psychological, and behavioral adaptations for aggression specifically in men (Goldstein 2001; McDonald et al. 2012; Sell et al. 2012). Male-male homicide is committed for a variety of reasons including the escalation of petty disputes, reputation management, and – most often – because of intrasexual competition (Daly and Wilson 1988).

Spousal homicides are overwhelmingly committed by men and are most often fueled by sexual jealousy, with young, reproductive age women disproportionately represented among the victims (Shackelford et al. 2000). Men may benefit from wife-killing if the wife has committed sexual infidelity which disposes risk of investing resources into genetically unrelated offspring. Men with adulterous wives may also incur substantive reputational costs which may be alleviated by uxoricide.

Men and women are both hypothesized to have evolved adaptations for the killing of infants, though for different reasons (Duntley and Buss 2005, 2011). Because internal fertilization and gestation occur in women, ancestral men could not be certain of the genetic relatedness of their offspring. Men with low paternity confidence are at increased risk for killing their offspring. Men that enter a relationship with women who have offspring from a previous mateship(s) may kill the women's offspring to reduce resource expenditure on genetically unrelated offspring and increase the

likelihood of subsequent breeding – a pattern found in nonhuman species, such as lions (*Panthera leo*; e.g., Packer and Pusey 1983). Women, in contrast are certain of maternity but may kill their offspring they perceive a net cost of continued investment (e.g., severely ill or deformed offspring) or if there are not sufficient resources to adequately care for the offspring (e.g., food scarcity). Infanticide may be considered a particularly powerful force driving its own set of adaptations in males and females (See ► [Infanticide](#), ► [Infanticide in Nonhumans](#), Infanticide as a Selective Force for Group Living, Infanticide Risk).

Other lines of evidence converge to support the key proposition that adaptations for killing conspecifics has evolved (reviewed in Duntley and Buss 2011), such as it being more likely that an individual's killer is someone known to the victim, cross-species documentation of killing conspecifics in similar and predictable contexts to those of humans, evidence on ancient human remains that are consistent with homicide by another human with a weapon, archeological evidence of weapons designed for homicide, extensive cross-cultural evidence of homicide, and consistency of contexts for homicide across diverse cultures. Taken together, existing evidence suggests the longevity of killing conspecifics in human and nonhuman evolutionary history.

Conclusion

Humans have a long evolutionary history of aggression (Pinker 2011). Duntley and Buss's (2011) homicide adaptation theory explains how homicide has evolved. The theory proposes that humans have evolved psychological mechanisms for killing. Homicide may have emerged as an advantageous strategy in specific contexts when the fitness benefits of committing homicide outweighed the fitness costs. These benefits suggest explanations for the cross-cultural and cross-generational ubiquity of homicide in humans.

Definition

Homicide by design is the premeditated killing of another person that is calculated and deliberate.

Introduction

Homicide is regarded by society as one of the most extreme and immoral crimes a person can commit. However, the act has persisted throughout human history and its prevalence is still unmistakably common today. Types of homicide (and human aggression in general) can be understood in two distinct groups: proactive and reactive. Reactive homicide entails an individual committing murder as a direct reaction to someone else's actions (Wrangham 2017). Common occurrences of reactive homicide include self-

defense and “heat of passion” murders. Conversely, proactive homicides lack the same emotion and physiological arousal as reactive murders (Wrangham 2017). They are premeditated, being consciously calculated by the offender against a specific individual or group of victims. This form of murder is also referred to as homicide by design, and its evolutionary advantages date as far back as the very beginnings of human history.

Homicide Adaptation Theory

Historically, homicide by design was an effective and adaptive method of solving evolutionary problems present in hunter-and-gatherer cultures and early human civilizations. The benefits gained from strategically killing others included preventing one’s own death, eliminating rivals, and acquiring valuable resources (Buss and Duntley 2001). In addition, the very limited or complete lack of legal and judicial repercussions in these times resulted in aggressive acts such as homicide enjoying these many evolutionary payoffs while avoiding the negative consequences these crimes face today. This theory was developed by Duntley and Buss (2011), who named it Homicide Adaptation Theory.

Homicide Adaptation Theory explains and predicts many statistics of today’s homicide prevalence, especially in the case of sex differences. For instance, the theory details why homicide rates are much higher in males (87%) and why males are also more likely than females to be the victims of homicide (75%): the early adaptive gains from homicide by design were mostly experienced by males, as they were the ones competing against each other to earn mates and obtain resources (Duntley and Buss 2011). Males who were better at planning their calculated attacks and successfully eliminating rivals would have thrived in this time period. Thus, the adaptive traits linked to homicidal ideation and planning would have survived and been passed on to future generations of males.

Ideation and Design

Even today, homicidal ideation is still a common occurrence in humans. Most people fantasize about killing at some point, even if they have no intentions or desire to follow through with their thoughts. These ideations often include detailed scenarios in which the individual contemplates and calculates the possible methods and consequences of their plan (Buss 2006). When faced today against a rival for adaptive resources such as access to food, mates, or money, the initial thought may be to strategically plan a way to eliminate the competitor entirely. The vast majority of people suppress homicidal thoughts and never commit or attempt murder due to the high risk of costly consequences following these acts. This suggests that homicidal ideations come from leftover psychological pathways from our ancestors which cause people to consider murder as a solution to different adaptive problems (Buss 2006). Despite premeditated murder now having more evolutionary costs than ever before, homicidal ideation in humans has not dissipated accordingly. Rather, the new consequences often force individuals to rethink their homicidal strategy and develop a different plan to solve their evolutionary problems.

Signal Affects

Individuals committing homicide can also benefit from more indirect evolutionary rewards, one of which being signal effects (Dahlén and Söderlund 2012). Somewhat counterintuitively, infamous murderers in recent human history such as Ted Bundy and Charles Manson achieved fame and even admiration from people all across the world. At first thought, it may be hard to understand why these criminals are admired and seen in a positive light despite committing heinous and immoral deeds; however, evolutionary perspectives of psychology explain that the killings can operate as a signal of the individual’s fitness, augmenting others’ perception of that person. The “homicidol effect,” coined by Dahlén and Söderlund (2012), described that individuals aligning themselves

with another individual prone to commit homicidal acts was evolutionarily adaptive and likely developed during ancestral times. By associating with a known and proven killer, the individual decreases the likelihood of becoming the culprit's next homicide victim, thus improving the individual's own fitness and chance of survival.

Conclusion

Despite being one of the most socially and morally impermissible acts a human commit, planned homicide has persisted throughout human history and still remains common today. The adaptive benefits and lack of costs of homicide in hunter gatherer cultures likely played a large part in wiring homicidal ideation into human brains through evolution over many generations. Committing homicide in this time also involved acquiring more indirect adaptive benefits including signal effects. While the costs and risks of homicide are much greater in today's world, ideation carries on, suggesting that the primitive drive to kill may be deeply rooted in our genes.

Homicide Fantasies and Evolved Homicide Module Theory

Homicide refers to the intentional act of killing another human. Buss and colleagues (Buss and Duntley 2001; Buss 2006; Duntley and Buss 2011) proposed that homicide is an evolutionary adaptation (i.e., *Evolved Homicide Module Theory* or *Homicide Adaptation Theory*). Psychological factors, such as cognitions or behaviors, are adaptive when they function to resolve challenges, leading to increased fitness. In human evolutionary history, there have been specific contexts where killing another human may have solved specific, recurring problems, and such actions had fitness benefits that outweighed the costs (Duntley and Buss 2006, 2008, 2011). Homicide was hypothesized to arise as an adaptation to prevent premature death, remove cost-inflicting rivals, gain resources, abort rival's prenatal offspring, eliminate stepchildren, and reduce future competitors of one's children (Duntley and Buss 2008, 2011).

One approach to studying homicide as an adaptation is through homicide fantasies. Our ability to form cognitions or fantasies about homicide suggests it allows people to explore scenarios in which murder may be a beneficial solution. Because these adaptive problems are complex (e.g., kin retribution), it would be important for mechanisms to weigh all the potential costs and benefits, resulting in either motivation or inhibition of homicidal behavior (Duntley and Buss 2006, 2008; Duntley 2005; Liddle et al. 2012; Shackelford et al. 2000). Since the homicide mechanism is triggered under specific contexts, this type of adaptation is considered facultative

and developmentally flexible. Buss and colleagues collected data on homicide fantasies from a very large sample (approximately 5000) across multiple nations. Generally, they found homicide fantasies to be quite prevalent, where 91% of men and 84% of women have had at least one homicide fantasy. These data also show some support for homicide as a facultative response to specific conditions. For example, Buss and Duntley hypothesized that spousal homicide functions by preventing being labelled a cuckold and reducing a rival's mating opportunities and found that many spousal homicide fantasies involved estrangement or infidelity (Buss 2006). Others studies found patterns of homicide fantasies that match patterns found in actual homicides, such as sex differences (Kenrick and Sheets 1993).

An alternative view is that homicide may function as a by-product of other adaptations (see, e.g., ► [Spousal Abuse and Homicide: Evolved Homicide Module Theory \(Buss\) \[Spousal Homicide\] \[Daly & Wilson\] entry](#)). Much more empirical and theoretical work is needed to test whether various types of homicide are adaptive or a by-product of other adaptations. These studies need to demonstrate that homicide has fitness benefits that outweigh the many costs.

Definition

The evolution of *Homo sapiens*, its ancestors, and closely related species from the last common ancestor with chimpanzees onward (~7 million years ago to present).

Introduction

Early evolutionary biologists answered the question of human origins by searching for the precise location of “man’s place in nature,” in T.H. Huxley’s phrasing, based on comparative anatomy between living species. Research has moved from viewing humanity at the top of the *scala naturae* to seeing it as “just” a big-brained, bipedal primate, and the focus shifted to explaining how we *arrived* at “our” place. The post-nineteenth-century focus has been on understanding the evolutionary circumstances that produced *Homo sapiens*, based on the idea that human-specific traits are the product of the same evolutionary processes that led to all other species. This effort is notably multidisciplinary: human origins fall within the remit of anthropology, biology, genetics, zoology, primatology, geology, and psychology. The (occasionally contentious) synthesis of work within these fields has produced a coherent, albeit pixelated picture, of which this summary is a sketch. It first reviews hominin evolutionary history chronologically and then explores evolutionary patterns, including the evolution of cognition, in more depth.

Hominin Evolutionary History

Hominins in Comparative Perspective

Systematics of the Primates

The Order Primates, to which we belong, is characterized by increased body size, dexterous hands, flexible limbs, nails instead of claws, a shortened snout, and associated shift of emphasis from olfactory to visual sensitivity manifested in, for example, stereoscopic vision. Primates are divided into two groups, separated terminologically if rather prosaically by nasal dampness: Strepsirhini (“wet-nosed”) and Haplorhini (“dry-nosed”) (fig. 1). This division

was initially based on purely morphological characteristics and was later refined and confirmed using molecular and genetic data. The Strepsirhini, whose ranks comprise lemurs and lorises, are characterized mostly by nocturnal adaptations (e.g., eyes with reflective layers to improve night vision), heightened olfactory sensitivity, and comparatively small brains. The Haplorhini are split into three major taxa: tarsiers, platyrrhines, and catarrhines. Current genetic phylogenies place tarsiers within the Haplorhini despite their strepsirrhine-like features, but their evolutionary relationship has been debated. The monkey-grade, or simian, primates are again distinguished nasally, but this time by shape: they include platyrrhines (“flat-nosed”) and catarrhines (“down-nosed”). Platyrrhines – of which the only living representatives is the Ceboidea superfamily which includes capuchins, marmosets, and howler monkeys – are restricted to the New World. They are mostly arboreal and are the only group to include monkeys with prehensile tails. Catarrhines, by contrast, are found in Africa and Asia: these are the Old World monkeys (Cercopithecoidea) and apes (Hominoidea). The Old World monkeys are unlike the apes in that they have tails, and include baboons, mandrills, and macaques. The Hominoidea comprises the arboreally specialized lesser apes (gibbons, or Hylobatidae) and great apes (Hominidae). Humans are therefore catarrhines, hominoids, and hominids.

Outline of Primate Evolution

There is an element of arbitrariness inherent in the idea of a “beginning” of the evolution of a lineage: after all, evolution is a continuous process, and consequently there are no real starting points within it. For this reason, the evolutionary events (like the splitting of lineages) requiring chronological estimates are based on *taxonomic* frameworks.

The current chronological outline of primate evolution is based on convergences between anatomical, fossil, and molecular approaches, of which the “molecular clock” gives the most frequently used dates. By assuming a constant rate of mutation during evolution, the molecular clock uses similarities and differences between biomolecules to estimate lineage-split times. The

Hominin Evolution,**Fig. 1** Phylogeny of living primates

divergence between primates and closely related lineages is estimated somewhere between 70 and 80 Ma, in the Cretaceous epoch. The Strepsirhini and Haplorhini diverged from each other around 55–90 Ma, and recent genetic estimates suggest they last shared a common ancestor ~87 Ma, at the very beginning of the primate radiation. Debate continues about the most likely location of their common ancestor – but Asia is a strong contender, because the basal clades of both lineages (the haplorhine tarsiers and strepsirrhine lorises), as well as the closest relatives of primates, Dermoptera and Scandentia, are exclusive to Asia. Fossil evidence of this common ancestor remains elusive. Tarsiers diverged from the rest of the Haplorhini early, around ~81 Ma. Platyrrhines last shared a common ancestor with catarrhines ~43 Ma, but the fossil record is equivocal

about where this last common ancestor lived and the platyrrhine route of dispersal to the Americas is therefore also unclear. Platyrrhines remained entirely arboreal, whereas some catarrhines (including humans) adapted to a terrestrial life. The Catarrhini further subdivided into Cercopithecoidea and Hominoidea ~25 Ma. Within the Hominoidea, the consensus order of divergence is an early Hylobatidae (gibbon) split with the rest of the clade at ~21 Ma, followed by *Pongo* (orangutan) at ~15 Ma and *Gorilla* at 8–9 Ma, and a final split between the *Pan* (chimpanzee and bonobo) and *Homo* lineages between 6 and 7 Ma.

Hominin Relationships to African Apes

Collectively, all modern and extinct great apes, including humans, are currently referred to as

hominids. The African contingent of the family Hominidae (comprising *Homo*, *Pan*, and *Gorilla*) is known as the subfamily Homininae. Within the Homininae there are three tribes: Gorillini, Panini, and Hominini. Humans are therefore most closely related to the two *Pan* species, chimpanzees and bonobos

Previously, “hominid” was also used to refer to the human lineage, including our ancestors and related species, after the split from *Pan*; but nowadays, humans and extinct species more closely related to humans than *Pan* are known as *hominins* (see Fig. 2). In practice, this means that we can start speaking of hominins around 7 million years ago, since molecular dates suggest the Hominini-Panini lineages diverged around this time – although the proposed split times range from 13 to 5 Ma.

Implications for Hominin Origins

In the context of the range of living species, hominins share the closest evolutionary history with the African apes and in particular with chimpanzees and bonobos. This evolutionary proximity implies that features we have in common with all Hominidae genera are the consequence of shared ancestry. The list of shared features, which were presumably present in our common ancestors, has expanded considerably over recent years and now includes behavioral traits, potentially including a capacity for “cultural,” or socially transmitted, behavior (Whiten 2011).

The features *not* shared with African apes are most probably the product of our lineage’s evolution after it diverged from our modern ape cousins’ lineages – in other words, the features

H

Hominin Evolution,

Fig. 2 Hominin relationships to African apes. Within the family Hominidae, the African apes, or Homininae, comprise three tribes: Gorillini, Panini, and Hominini. The term *hominid* is used to refer to all great apes, while *hominin* refers to humans, the direct ancestors of humans, and other closely related species *after* the split from *Pan*

that arose specifically during hominin evolution. In this perspective, it is implicit that some features unique to other ape genera are the consequence of their independent evolution, so apes cannot always be used as direct analogues or homologues for human ancestors. This phylogenetic framework is essential in exploring the origins of hominin characteristics, as it is a precursor to discovering *why* and *when* these “human” features appeared and what *consequences* they had.

Environmental Context for Hominin Evolution

The problems to which hominin adaptations provide solutions derive from the physical environment: the ecological context in which hominins evolved. Hominins diverged from the Panini clade at the end of the Miocene (23–5.3 Ma), around 7 Ma. Important climatic changes coincide with their emergence: long-term decline in temperatures (culminating in Pleistocene Ice Ages) and associated fragmentation of habitats (involving the breaking up of Miocene tropical forests and expansion of grassland, woodland, and bushland, producing mosaic habitats). These more open environments played significant roles in hominin evolution. Furthermore, the increased fragmentation probably promoted speciation through population isolation and also produced dynamically changing selective pressures associated with changing resource type, distribution, and seasonality.

Hominin Origins

The Hominini-Panini split is poorly documented in the fossil record, reflecting an overall paucity of Miocene fossils. Hominin origins consequently remain an elusive paleoanthropological problem. The problem has two key elements: first, the environmental and evolutionary context in which the split and, second, the lineages involved – the last common ancestor (LCA) of humans and chimpanzees, and its daughter species, the earliest member of the hominin clade.

To date, no potential chimpanzee-human LCA is known from the fossil record. This precludes empirical reconstruction of the context in which

the ancestral species split into two independent lineages. Even the geographical context of that group is unclear; although hominins belong to the African ape clade, and this clade might have a prolonged African ancestry, an alternative scenario is a Eurasian ancestor that migrated back into Africa in the Late Miocene. Two potential Eurasian ancestors have been proposed: *Graecopithecus* and *Ouranopithecus* – but there is insufficient fossil material to conclusively resolve the issue.

There are three African Late Miocene contenders for “early hominin” status: *Sahelanthropus tchadensis* (7.43–6.38 Ma), *Orrorin tugenensis* (6.14–5.52 Ma), and *Ardipithecus* (6.7–4.26 Ma). These three genera are classed as potential basal members of the hominin clade due to probable bipedal adaptations and, where sufficient evidence, dental traits shared with later hominins. Found in Chad, *Sahelanthropus* has an anteriorly positioned foramen magnum (the opening at the base of the cranium through which the spinal cord passes) compared to quadrupedal species, indicating that its head was held on an upright body consistent with some level of bipedal locomotion. However, the incomplete nature of the fossil makes reconstruction of the position of its foramen magnum, along with the behavioral inferences based upon it, contentious. By contrast, East African *Orrorin* is only known from fragmentary postcrania. Its femoral morphology suggests it shared distinctive hip biomechanics with the unequivocally bipedal australopithecines (Richmond and Jungers 2008). Finally, *Ardipithecus*, an Ethiopian genus comprising two species (*ramidus* and *kadabba*), shows a mosaic of terrestrial and arboreal features, indicating it was a facultative biped – in other words, that it moved bipedally on the ground, but quadrupedally in trees. Dentally, *Ardipithecus* showed reduced sexual dimorphism of the upper canine: a hallmark of later hominins, contrasting with marked canine sexual dimorphism in chimpanzees.

Opinions are divided about early hominin taxonomy: the fossils may represent three individual genera, may belong to one basal hominin genus, may not belong to the hominin clade at all, or a

combination of these. The real difficulty in assigning Late Miocene apes to a species, genus, or lineage is not just ascertaining the presence or absence of derived traits shared with later hominins, as their evolution may have been paraphyletic. The divergence of later Miocene African hominids may have involved complex speciation with prolonged gene flow among populations and the evolution of extinct lineages with no direct ancestral relationship to later hominids. Further uncertainties about genetic mutation rates and generation times compound these paleontological considerations, because they influence molecular clock split-time calculations. Slow mutation rates produce dates as early as ~13 mya for the Hominini-Panini split, while fast ones estimate it at ~5 mya.

Early Hominin Evolution

Early hominin evolution (~4.2–2 Ma) is usually taken as synonymous with the emergence, diversification, and partial extinction of the australopithecines, defined broadly (see Table 1). This is correct, in a sense, although there is no clear consensus as to which early hominin species should be included formally in *Australopithecus*. The period might have seen the emergence of at least two other genera: *Paranthropus* (sometimes referred to as the “robust” australopithecines) and *Kenyanthropus*. The exact nature and extent of taxonomic diversity is debated; some researchers advocate a minimal level, but most support at least some degree of diversification. The evolutionary history of the early hominins coincides with the early Pliocene and

consequently takes place in the context of increasing habitat fragmentation. In this ecological context, the high degree of species diversity (however it is interpreted taxonomically) during this period is frequently interpreted as an adaptive radiation, although the scale, relative to other primate groups, is relatively small.

As a whole, this diverse group shares bipedal adaptations, reduced canines and canine sexual dimorphism, relatively large postcanine dentition, apelike life histories, body sizes, and cranial capacities. Broadly speaking, the latter three remain relatively constant across early hominin species (see Table 1), while the first two contribute to the fundamental trends underlying australopithecine diversity. These are:

1. Varying levels of terrestriality, with morphological adaptations to ground-dwelling. Mosaics of locomotor features are indicative of a spectrum of bipedal adaptation, with species incorporating arboreal climbing in their locomotor repertoire to greater or lesser degrees. *Au. afarensis*, a well-represented species (with around 300 individuals found so far) that lived from 3.89–2.9 Ma, has clear derived bipedal adaptations, like a humanlike pelvis and non-grasping big toe, but also primitive features indicative of arboreality, like long, curved fingers and a strong shoulders. A set of footprints found in Laetoli, Tanzania, dated to ~3.7 Ma and likely made by *Au. afarensis*, are commonly interpreted as the product of a form of bipedalism not unlike that of modern humans (Raichlen et al. 2010). *Au. africanus* (4.02–1.9 Ma) provides evidence of an increased reliance on arboreality than its older relative, with a grasping big toe and longer arm to leg ratio. *Au. sediba* (1.98 Ma) moved with a distinct combination of arboreal and terrestrial features, again implying a unique form of bipedalism (Zipfel et al. 2011). So, while early hominins were clearly united in their increased reliance on bipedal locomotion compared to their Miocene ancestors, accumulating evidence suggests at considerable diversity the *nature* and *degree* of bipedalism each species exhibited.
2. Specialization of subsistence behavior with a trend toward postcanine megadonty. The general “australopithecine” trend toward postcanine megadonty reflects increasing specialization in subsistence behavior over ~2 million years. From an ecological perspective, this makes sense: as new environments (such as those resulting from decreasing temperatures in the Pliocene) become saturated with opportunistic species, the evolutionary advantage shifts to specialized species who extract energy from specific resources more efficiently (Foley 1987). Subsistence specialization is especially pronounced in *Paranthropus* (later “robust” Australopithecines (*aethiopicus*, *boisei*, and *robustus*), ranging from 2.73 to 0.87 Ma), which share adaptations for chewing extremely hard and brittle foods like nuts and seeds. These adaptations include prominent sagittal crests for the attachment of massive chewing muscles, large and robust cheekbones to accommodate these muscles, and thick dental enamel. Some researchers consider their degree of subsistence specialization sufficiently different to that of the “gracile” Australopithecines to suggest they are a separate genus, *Paranthropus*, in accordance with one definition of a genus as a clade sharing a single adaptive zone (Wood and Collard 1999).

The Origins of *Homo*

The exact ancestry of *Homo* is unclear, but the genus tends to be seen as the evolutionary product of the gracile australopithecines. In general, *Homo* differs from *Australopithecus* in its trend toward ecological generalism, reflected in efficient ranging behavior, encephalization, and behavioral flexibility. The candidates at the center of the debate about the origin of our genus, which first appears at the start of the Pleistocene (2.5–0.01 Ma), are *Homo habilis* (2.6–1.65 Ma) and *Homo rudolfensis* (2.09–1.78 Ma). Their status as members of *Homo* is contentious. The problems with assigning fossils from around 2 Ma to either *Homo* or *Australopithecus* are twofold: first, the process of macroevolution and, second, uncertainty regarding the exact defining characteristics of the *Homo* genus.

In a now familiar tune, exact taxonomic affinities between species around this time are hotly debated. This derives, in part, from the debated definition of “genus” in the context of macroevolution, where the central question is *when* differences between species or groups of species are sufficient to merit their distinction at the generic level and of what *nature* these differences should be. A character-based distinction between *Homo* and *Australopithecus* – where *Homo* is defined on the basis of enlarged absolute brain size ($>600\text{ cm}^3$) and “complex” behavior, including tool use and language – long formed the bedrock of investigation into the origins of *Homo*. This essentially amounts to a “checklist” of features true *Homo* species should exhibit, but its validity has been questioned in recent years.

On the one hand, the apparent simplicity of a trait list for *Homo* membership is deceptive, because inferring the presence or absence of “complex” behavior is difficult. Language leaves no direct trace in the fossil record, and no stone tools have so far been found associated directly with Pliocene hominins. In the context of multiple coexisting hominin species around 2 Ma, this precludes assigning makers to lithic assemblages. The synonymy of technological ability and the *Homo* genus, moreover, is an artifact of the incomplete archaeological record: until 2015 the earliest known stone tool industry was the Oldowan, dated to 2.5 Ma, coincident with the appearance of the first bigger-brained hominin species (*H. habilis*). The beginning of the archaeological record has now been pushed back to 3.3 Ma with the discovery of the Lomekwian industry (Harmand et al. 2015), implying either that *Homo* originated much earlier in hominin evolution or, more parsimoniously, that the evolution of technological behavior preceded the emergence of our genus. Simple stone tool use by chimpanzees and capuchins in order to crack nuts supports the latter.

On the other hand, the usefulness of a trait checklist is undermined because it oversimplifies distinctions between genera by assuming a definable moment in time at which these distinctions appeared. This might not have been the case, and it has recently been suggested that the abrupt

Homo-Australopithecus divide that the checklist approach is based on has been exaggerated and that the emergence of *Homo* from *Australopithecus* is better conceived of as an accumulation of small transitions (Foley 2016).

So, theoretical problems abound. What this means in practice for the putative earliest members of *Homo*, *habilis* and *rudolfensis*, is that they likely represent “intermediate” species between *Australopithecus* and *Homo*, with features linking them to both genera. They have larger absolute brain sizes than Australopithecines and likely made and used stone tools, but the *habilis* hand and foot indicate it might have retained some arboreality in its locomotive repertoire. Both species have been suggested to have similar life histories to Australopithecines and certainly have considerably smaller bodies than later *Homo*. A phylogenetic approach to *Homo* by Wood and Collard (1999), where they define a genus as a “monophylum [common ancestor and all descendants] whose members occupy a single adaptive zone,” suggested *habilis* and *rudolfensis* do not belong in the genus. In summary, the emergence of *Homo* appears to be characterized by greater complexity than previously assumed.

The Evolution of *Homo* in the Pleistocene

After 2 Ma, human evolution is characterized by a general trend toward bigger brains, reduced dentition, increased technological complexity, and the development of a body plan adapted for long-distance ranging (see Table 2 for a list of *Homo* species after 2 Ma). The development of these traits contributed to the first hominin dispersals out of Africa, currently estimated at ~1.8 Ma. Despite these distinct overall patterns, specific evolutionary relationships between hominins in this period are unclear.

While its membership to the *Homo* genus is uncontested (based on its large brain, tool use, and modern body proportions), the precise phylogenetic affinities of *Homo erectus* are not. Its ancestry, descendants, and classification are debated, especially in relation to *Homo ergaster*, which is exclusively found in Africa. Some researchers assign *ergaster* and *erectus* to a single evolving lineage, called *Homo erectus*; others support a

*indicates this is debated; see text for discussion. Shaded species have been proposed as the earliest members of *Homo*, but their exact phylogenetic affinities are uncertain

variation on this argument, where *ergaster* is the “African variety” of *erectus*. From this perspective, *Homo erectus* sensu lato (s.l.) refers to the lineage as a whole, whereas *Homo erectus* sensu stricto (s.s.) is used to refer to its Asian representatives (Lordkipanidze et al. 2013). Alternatively, *Homo erectus* and *Homo ergaster* can be seen as two distinct species, where *ergaster* is older and African and *H. erectus* younger and Asian (Klein 1999). These contrasting perspectives are based on interpretations of morphological variation between fossil groupings (with the unresolved issue being how much variation can be exhibited within a distinct species unit). An unusually large set of contemporaneous hominins found together in Dmanisi, Georgia, illustrates the complexity. The site was inhabited from 1.8 to 1.7 Ma

(making these the earliest hominin fossils outside Africa), and its inhabitants exhibit wide morphological variation with features linking them to *H. habilis*, *H. ergaster*, and *H. erectus* (s.s.). This mosaic suite of features, combined with the range of variation, it has been suggested, shows a single evolving *Homo* lineage with some geographically stratified variation around 1.8 Ma (Lordkipanidze et al. 2013). However, across the range of possible *Homo* paleodemes of the Lower Pleistocene, it is likely that several lineages existed in relative geographical isolation, some becoming established as stable species – for example, *Homo erectus*.

Regardless of systematics, the *Homo* lineage is characterized as a whole by fully modern (i.e., humanlike) bipedalism reflected in a rounded pelvis, long legs relative to arms, and arched feet, as

well as reduced postcanine dentition and large brains (~900 cm³). They made simple (Mode 1) stone tools and might have used fire.

Whatever their ultimate phylogenetic status, hominins first dispersed out of Africa in the Lower Pleistocene. The earliest evidence possible claim for a dispersal are some disputed stone tools from Pakistan (Dennell et al. 1988), at around 2 Ma; a less contested earliest date outside of Africa are from the hominin remains at Dmanisi (1.8 Ma) and lithic assemblages in Israel (1.9–1.7 Ma). There is considerable uncertainty about the timing, route, and direction of early hominin dispersals, but archaeological evidence implies at least three waves of migrations. The first, around 1.8 Ma, involved the makers of Oldowan core-chopper tools; the second, around 1.4 Ma, makers of Acheulean hand axes; and the third, around 0.8 Ma, is represented by Acheulean assemblages with numerous flake cleavers. It is commonly proposed that these dispersals were facilitated by behavioral flexibility (manifested in greater levels of hunting and cooperation and dependence upon technology) resulting from increased intelligence, as well as changes in body plan reflecting adaptations for long-range walking.

The best-known later descendant of these dispersing hominins is the larger-brained *Homo heidelbergensis* (0.7–0.1 Ma). As a whole, this species was larger than preceding hominins, stockily built, and had thick cranial bones and massive brow ridges. Its brain size was almost as large as that of modern humans at around 1200 cm³, although its encephalization quotient (the allometric relationship between the brain and body size) is smaller. Technologically, it is associated with the Acheulean industry (Mode 2) and is likely to have hunted and potentially cooked its food. Its relationship to later hominins is controversial. *H. heidelbergensis* is known from Africa and Eurasia and is sometimes divided into geographical lineages (*H. heidelbergensis* and *H. rhodesiensis*). Whether they are a single species or two, *H. heidelbergensis* represents the core Middle Pleistocene lineage, widespread across the Old World and ancestral in some way to the later hominin lineages in Africa and Eurasia; namely, modern humans and Neanderthals.

Later *Homo* Diversity

Late Pleistocene species and their evolutionary relationships are relatively well understood, no doubt because they are better well represented in the fossil record, and more significantly because they existed recently enough for ancient DNA to be preserved. There are three lineages of later Pleistocene hominin currently recognized – Neanderthals, Denisovans, and *Homo sapiens*. The first two are Eurasian, the last African, and all evolved in the last ~300 ky or more.

The Neanderthals are the best-known extinct hominin, and past misconceptions unfairly characterized them in Hobbesian terms as “nasty, brutish, and short.” Relatively short they might have been – they were stockily built, with males averaging 166 cm and females 154 cm – but the archaeological record associated with them suggests they were capable of behaviors that are very similar to those of modern humans. Key questions about Neanderthals concern the degree of behavioral complexity they were capable of and the nature of their distinct morphological features. Anatomically, Neanderthals appear particularly well-adapted to cold Pleistocene European climates: their limb proportions appear to conform to Allen’s Rule (cold-adapted species tend to have short limbs), and their shape and relative robusticity conforms to Bergmann’s Rule (bodies tend to be rounder in colder climates). Neanderthal facial features have also been explained with reference to climate: for example, their relatively large sinuses could have been useful for warming inhaled air. However, this explanation has been challenged, and the distinctive Neanderthal morphology might simply be the consequence of genetic drift in an isolated population.

Neanderthals made standardized stone tools, but this is where consensus about their behavioral repertoire ends. Broadly speaking, there are two major positions: one contends they lacked behavioral flexibility, did not have language, did not bury their dead, did not use fire, and scavenged rather than hunted, and the other suggests the opposite. Current evidence best supports a mild version of the latter. Neanderthal genomes contain the human version of the

speech-related FOXP2 gene, and the Kebara Neanderthal hyoid bone shows features consistent with a capacity for speech – although these features do not necessarily imply “modern” language. Archaeological evidence suggests at proficient hunting: the oldest known wooden spears in Europe date to 300 kya, and lithic spear points date as far back as 185 kya. Claims for advanced “cultural” capacities have been based primarily on the French Châtelperronian industry, which included ivory rings, grooved and perforated animal teeth, and other potential ornaments, but this has been contested on the basis of likely stratigraphic mixing (Higham et al. 2010). It appears Neanderthals used bird feathers, perhaps for decorative purposes. Controversial archaeological evidence aside, their large brains and similar encephalization quotient to humans make it unlikely Neanderthals were incapable of at least *some* “advanced” behavior.

The Neanderthals were not the only Eurasian hominin lineage. The “Denisovans” were first introduced to the paleoanthropological lexicon by Reich and colleagues in 2010, following the successful sequencing of ancient mitochondrial and nuclear DNA extracted from a distal manual phalanx found in southern Siberia. Based on the aDNA evidence, which suggested the individual belonged to a sister group of Neanderthals, the group was named Denisovans after the cave in which their remains were found. So far, they are represented by very fragmented and undiagnostic anatomical elements, and so their phenotype is unknown, but they may have been widespread over large parts of East Asia. When both are compared to modern human genomes, the Denisovan has an unexpected excess of divergent regions in comparison with its Neanderthal sister species, leading Prüfer and others (2014) to propose that these regions could have been contributed by an as yet unidentified species. Alternatively, the similarity between Neanderthals and modern humans might be the result of gene flow from AMHs into Neanderthals, and this is a more parsimonious explanation (Posth et al. 2017).

The Evolution of Modern Humans

It is now almost universally accepted that while Neanderthals and Denisovans evolved in Eurasia, *Homo sapiens*’ roots lie in Africa. This is known as the “Out of Africa” model, in which AMHs are a distinct African species that replaced existing Eurasian hominins as it dispersed out of Africa around 50 kya. Earlier models proposed a more widespread evolution of modern human traits, with regional continuity from archaic to modern forms, rather than dispersals and replacement. Genetic studies have formed the basis for the Out of Africa model.

Genetic Evidence

The coalescence date of the modern human and Neanderthal lineages gives a lower bound for our species’ independent genetic history. Prüfer et al. (2014) suggest a date of 553–589 kya based on two Neanderthal genomes. All lines of genetic evidence point toward an African origin of AMHs. The highest level of mitochondrial DNA diversity is found in Africa, which can be explained as a result of African populations having a longer period of time to accumulate genetic diversity compared to the populations of AMHs that colonized the rest of the world *after* their emergence in Africa. Mitochondrial DNA lineages coalesce ~200 kya (implying their LCA lived around this time), in accordance with fossil evidence. The same goes for the Y chromosome, although it coalesces at ~150 kya (Jobling et al. 2014). The relatively low amount of whole-genome genetic variation worldwide compared with, for example, chimpanzees, is suggestive of a relatively small founding population resulting from a genetic bottleneck associated with the AMH migration out of Africa.

Fossil Evidence

The oldest fossils showing significant *Homo sapiens* traits are found in Africa: in Jebel Irhoud, Morocco (300 kya); Omo, Ethiopia (195 kya); Herto, Ethiopia (160 kya); and Laetoli, Tanzania (120 kya). Some of these are clearly AMH, while others show mixed traits, suggesting a complex population history. Modern humans are characterized by a rounded cranium with a vertical

forehead and reduced brow ridges, a small orthognathic face, a chin, and a tall, relatively gracile skeleton. These earliest AMHs are considerably more robust than current forms, and they exhibit a mix of archaic and modern features concurring with an African origin.

Archaeological Evidence

There is a general association between the evolution of modern humans and the Middle Stone Age in Africa, although it is the case that both archaic forms in Africa and Neanderthals used Mode 3 technologies (see section “[Technology](#)”). The African archaeological record is dramatically understudied compared to its European counterpart, but despite this, more derived traits such as blades, use of ochre, and use of aquatic resources first occur between 280 and 120 kya in Africa, compared to around 50 kya in Eurasia.

A historically contentious concept is “behavioral modernity.” On the one hand, some scholars have argued the archaeological record is indicative of a mismatch between anatomical modernity and behavioral modernity. The most extreme variety of this standpoint is a “human revolution” where modern human culture, linguistic ability, and cognition suddenly appear at 50 kya, 150,000 years after the emergence of morphologically modern humans (e.g., Mithen [1998](#)). On the other hand, Mcbrearty and Brooks ([2000](#)) and others suggest there was a slow, sporadic development of modern human cognition in Africa over a period spanning at least 300,000 years; so, behavioral modernity evolved in tandem with its biological correlates (i.e., large brains and the modern human form). Current evidence supports the latter view, with increasing evidence for unambiguously symbolic behavior as early as 100 kya, and modern human cognition generally, as manifested in various technologies and subsistence behaviors, at ~250 kya (for a full discussion (McBrearty and Brooks [2000](#))).

Admixture Between Modern Humans and Archaic Hominins

Interbreeding between Late Pleistocene hominins appears to have been a common occurrence. At current count, there is genetic evidence for three to

five cases between four distinct populations (Prüfer et al. [2014](#)): between modern humans and Neanderthals, modern humans and Denisovans, Neanderthals and Denisovans, and Denisovans and an unknown hominin. The evidence for interbreeding is debated: it has been shown that ancient population substructure generates highly similar genetic patterns to gene flow, and the two scenarios are difficult to differentiate statistically. If assumptions hold, however, and the genetic patterns are the consequence of gene flow, coding sections of introgressed DNA can provide a clue as to the functional consequences of interbreeding. It looks, for example, like Neanderthals and Denisovans contributed immune system genes to modern Eurasian and Oceanian populations, and altitude adaptations in modern Tibetans have been linked to Denisovan-like DNA (Jobling et al. [2014](#)).

The Evolution of Human Diversity

The observed degree of modern human diversity depends on analytical category: on one end of the scale, sociocultural differences between human groups are vast (although all cultures share universal elements), while at the other, we are biologically relatively homogenous – at least compared to other great ape species. These discrepancies reflect differential rates and transmission of change: genetic evolution is transmitted from one generation to the next and is therefore limited by long human lifespans, while cultural change can occur many times within one lifetime and is transmitted both within *and* between generations. What biological variation does exist between human groups tends to be geographically stratified: that is, it is the consequence of populations’ individual genetic histories after dispersals into specific regions (or, in the case of Africa, remaining in a region). Although there is disagreement about exact timings, the history of continents’ colonization is summarized in Table 3. Population-specific traits, whether invisible (molecular) or visible (morphological), tend to be explained first with reference to specific ecological circumstances. Ethnic differences in hemoglobin genes are linked to geographic malaria persistence, and lighter skin has been

explained as a response to less intense sunshine in northern latitudes. Other processes, such as genetic drift or sexual selection, may have played an equally significant role: blonde hair, for example, confers no direct evolutionary benefit and has instead been shown to be the likely product of sexual selection.

The Out of Africa model of human evolution emphasizes the genetic homogeneity of humans as a species. Biological differences are thus relatively minor and are the product of differential dispersals, local adaptation, and genetic drift under conditions of isolation. Older models that related major racial divisions in the human population have been abandoned.

The Pattern of Hominin Evolution

Hominin evolution is not just a question of phylogenetic and phenotypic change, but is a pattern of adaptive change in response to changing ecological and selective conditions. The fossil record shows a sequence to these adaptive changes.

Bipedalism

Anatomically, obligate bipedalism is one of the most obvious and fundamental differences between our ape relatives and us. The consensus among paleoanthropologists is that bipedalism is a defining feature of the hominin clade and that adaptations for upright locomotion can be used to assign putative hominin fossils from 7 to 5 Ma to the lineage (see section “[Hominin Origins](#)”). Accumulating evidence suggests at multiple

“versions” of bipedalism in the hominin clade (see section “[Early Hominin Evolution](#)”). A key issue in the analysis of locomotor features is interpreting “primitive” arboreal traits shared with Miocene apes: these could be preserved due to functional relevance *or* be inconsequential vestigial remains that were not selected against. In any case, mosaics of locomotor features in early hominins imply bipedalism need not be monophyletic, meaning it could have evolved several times independently within a rapidly diversifying lineage.

The absence of early chimpanzee fossils complicates reconstruction of the precursor to hominin bipedalism. Suggestions for the ancestral condition have included a knuckle-walking ancestor, an orthograde arboreal clamberer, and pronograde clambering similar to orangutans. It is likely the LCA did not brachiate; the Miocene ape *Proconsul*, which likely belongs to the common ancestry of African apes, shows no adaptations to brachiation.

The question of *why* bipedalism evolved remains, and while as many as a dozen explanations have been proposed, they are united in their specific reference to the ecological context within which it did. This context was one of increasing habitat fragmentation. Energetic models suggest bipedalism allows the exploitation of larger areas than the knuckle-walking of modern chimpanzees, with obvious advantages in terms of food acquisition in patchy resource distributions associated with mosaic habitats. Others have suggested a bipedal posture was first habitually adopted in threat displays against predators or as a form of vigilance in increasingly open environments. Thermoregulatory advantages of reducing the surface area exposed to direct sunlight and raising the trunk further from the ground have also been proposed. A further possible advantage of bipedalism was that it freed the hands for carrying, an idea originally proposed by Darwin. These hypotheses are not necessarily mutually exclusive; indeed, it is likely selective pressures associated with changing environments produced multiple challenges (like increased predation, exposure to heat, and more dispersed resources) to which an upright posture provided evolutionary

solutions. And while it provided solutions, bipedalism also engendered energetic costs requiring explanation in comprehensive models of its origins.

Encephalization and Life History

If developing bipedalism is the defining feature of the earlier phase of hominin evolution, encephalization is that of the later phase. Encephalization entails brain growth beyond that *expected* for an animal's body size and is measured as a ratio of body size to brain size known as the encephalization quotient (EQ). High values imply greater intelligence as they reflect "more" brain than that required to merely coordinate bodily functions. Australopithecine brains stay relatively stable at chimpanzee-like volumes from ~4 to 2 Ma, contrasting with the increase observed in the *Homo* lineage (see Fig. 3). Even within the comparatively encephalized order Primates, *Homo* is exceptionally large-brained, and various adaptive explanations have been proposed to explain the trend (see section "The Costs of Cognition"). As with the evolution of bipedalism, these causal factors are not mutually exclusive,

and it is likely the ultimate selective pressure arose from their interactive effects.

Regardless of their evolutionary advantages, larger brains entail clear energetic costs (see section "The Costs of Cognition" for a full discussion) for parents and offspring alike. They require a longer period of postpartum growth to reach adult size because the narrow human birth canal, the product of selection for a rounded bipedal pelvis, limits the maximum brain volume attainable in utero. This period of growth creates increased and prolonged energetic demands, met by secondary altriciality – high and prolonged dependence on others, including conspecifics other than parents. The *Homo* "solution" to these demands is a changed life history (the timing of key events in an organism's life cycle). Human life histories differ from those of African apes in two key ways: they include a long period of childhood after weaning, and women live long after reproductive cessation. By contrast, female apes' physiological systems usually fail together with menopause. These life history shifts appear in tandem with encephalizing brains: analyses of dental and femoral development of fossil hominins have indicated that *Australopithecus* is

Hominin Evolution, Fig. 3 Hominin encephalization quotients. Data from Schulkin (2011)

more similar to African apes in its rate of development, whereas the development schedules of *Homo ergaster* and Neanderthals are more similar to that of *sapiens* (Smith 1994).

Technology

A key difference between extant primates and humans is our extreme reliance on technology for survival – while some primates (chimpanzees and capuchins) do use stones to crack nuts, there is no evidence (yet) of nonhumans purposefully manufacturing lithic tools in the wild. Technology is a specific trait within a species’ behavioral repertoire, but it is especially ecologically significant as it provides a foundation for other behavioral traits like hunting.

Lithic technology dominates most of human evolution; other raw materials, like bone, antler, and metals, were first used only relatively recently. Hominins have been making stone tools for at least 3 million years; the earliest simple flaked tools come from Lomekwi in Kenya and are dated to ~3.3 Ma (Harmand et al. 2015). Lithic technology has been classified in several ways reflecting technological, morphological, and stylistic differences, of which the most commonly used are Clarke’s (1968) technological modes. He recognizes five modes (see Table 4) which are very loosely arrangeable as a chronological framework cataloguing increasing complexity

over time, but with a very strong caveat: the modes overlap considerably, with the “simpler” modes occurring continuously after their first appearance, and the introduction of a novel technology often did not result in the complete replacement of older forms. Obviously, in the frequent absence of hominin fossils associated with lithic assemblages, it is challenging to generalize about species-specific technological abilities. Broadly speaking, however, the earliest simple flaked tools (represented by Mode 1) were manufactured by late australopithecines and early members of *Homo*; Mode 2 bifacially flaked hand axes are frequently associated with *Homo ergaster* and *Homo heidelbergensis*; and prepared core technologies (Modes 3 and 4) appear with later forms of *Homo*. Modes 4 and 5 are currently exclusively associated with AMHs. While increasingly complex technological manufacture probably reflects changing cognitive capacities to a great degree, especially in the context of progressively encephalized brains, it should be noted that lithic technology was likely only *one* component of early toolkits and “simple” technology is thus not necessarily synonymous with “simple” cognition. The long stasis of the Asian archaeological record associated with *Homo erectus* (s.l.) has been interpreted this way, for example, but it is highly likely they supplemented their lithic technology with other

locally available materials – possibly bamboo. *Homo heidelbergensis* definitely made wooden tools, evidenced by eight throwing spears from Germany dated to ~400 kya. Vegetation-based non-lithic technology was thus within the technological repertoire of species before *Homo sapiens*, but that based on materials such as bone and antler tends to be seen as evidence for increased behavioral complexity and intelligence, mainly because they are found only in association with AMHs.

Culture

Technology is one element, among many, of human culture. “Culture” is commonly seen as the sine qua non of our ecological niche as it is essentially a storage and transmission vehicle for human behavior. The comparative study of culture in an evolutionary context is an increasingly important field, one example of which is cultural primatology. Paleoanthropologists and cultural primatologists are concerned with, first, *when* and *why* “culture” evolved and second, its biological consequences.

The time depth of “culture,” as well as its evolutionary causes, is entirely subject to definition. Cultural primatologists operationally conceive of “culture” as a process, rather than a product: i.e., as information or behavior acquired from conspecifics through some form of social learning. This definition dramatically deposes human culture from its long-held pedestal of exclusivity in one sense, because in this conception culture can be attributed to other modern taxa such as killer whales and chimpanzees. Despite cultural behaviors in nonhumans, human culture remains unique in its scale and complexity, often summarized as the capacity for cumulative culture. The empirical question that follows on from this perspective is, “when did *human-specific* (cumulative) culture appear, and under what selective pressures?” Broadly, two models of cultural emergence prevail: one advocating a “revolution”: a relatively late sudden emergence of culture as a complete “package” associated with the development of language and consciousness (e.g., Mithen 1998). The other posits a gradual accretion of elements that comprise modern human culture

(e.g., Mcbrearty and Brooks 2000). The expanding archaeological record, especially as more evidence in Africa is discovered, tends to support an accretionary pattern, with some elements, potentially including symbolism, appearing before the emergence of AMHs, and others, like blade technology, appearing after. That said, it is true that human culture has markedly increased in complexity over the last ~10,000 years, and this probably reflects an important transition in cultural evolution, and equally that culture probably played relatively little role in the Pliocene and earliest Pleistocene phases of hominin evolution. If a tendency toward cumulative culture is a process that occurred in the last half million years or so, it raises the question of the “cultural status” of different hominins. The limited evidence of the archaeological record would certainly point to marked contrasts between modern humans and, for example, Acheulean-bearing *H. heidelbergensis*, but more subtle differences with Neanderthals, who may have shared considerable cultural complexity with AMHs.

The biological consequences of human culture are significant. By any standard, it is unique in the extent to which it has transformed our surroundings and thus our selective environment. This has contrasting evolutionary effects: on the one hand, it *removes* selective pressures (a culturally constructed environment buffers the genome from “natural” pressures, removing the need to genetically adapt to newly colonized habitats). On the other, it *creates* them, as the constructed environment exerts new evolutionary stresses culminating in gene-culture coevolution. The classic example of this process is lactase persistence in populations with pastoralist ancestry, where individuals in pastoralist communities who continued producing lactase would have been at a nutritional advantage.

Adaptive Radiations

The patterns in hominin evolution can be interpreted as seven adaptive radiations (Foley 2003), where an adaptive radiation is defined as (rapid) diversification of a group with common ancestry. These radiations are:

- (I) The African apes and earliest hominins in the later Miocene, the products of which are *Sahelanthropus*, *Orrorin*, and *Ardipithecus*.
- (II) The bipedal apes (early australopithecines), whose diversification mainly occurred within mosaics of locomotive features.
- (III) The megadontic specialists (the *Paranthropus* genus): it is unclear whether this was a monophyletic (single ancestor) group or the outcome of a general trend toward megadonty within the Australopithecines and, as such, whether it is a true radiation.
- (IV) The earliest *Homo*: this is the most problematic of the radiations, because the phylogenetic positions of the species within it are precarious (see section “[Hominin Origins](#)”), and it shows relatively little taxonomic diversity or scale of geographical dispersal.
- (V) Pleistocene *Homo*: specifically, *Homo erectus* (s.l.) and its descendants. Underlying this radiation is a major shift in adaptive complex, reflected in changes in morphology and behavior.
- (VI) Larger-brained *Homo*, in the last 0.5 Ma, with the emergence of the Neanderthals, Denisovans, and AMHs.
- (VII) The radiation of *Homo sapiens*, which mostly involved social rather than morphological diversification.

Hominin Diversity

These patterns are, in practice, more continuous, but emphasize the role of diversification and geographical spread in the process of becoming human, rather than the classic *scala naturae* of early reconstructions. The hominin family tree is now speciose, although this is subject to splitting/lumping controversies, where the underlying problem is one of variation – specifically, how much is acceptable between individuals classed as the same species. A splitting perspective would identify about 28 hominin species, and this does not seem unreasonable in the context of modern-day primate diversity (with approximately 60 genera and 200 species) (Fleagle [1995](#)).

Transitions in Hominin Evolution

An alternative way of making sense of these evolutionary patterns is as a series of transitions (within which adaptive radiations, or other degrees of evolutionary diversification, may have taken place). The question, here, is whether these major changes occur continuously or only during particular periods in prehistory. The distinction between *Homo* and *Australopithecus* is often seen as an important transition, but it is probably more accurate to recognize three major transitions (Foley [2016](#)). They are, in order:

1. Ranging and energetics (~5–4 Ma), with the appearance of habitual bipedalism and changes in ranging behavior as habitats became increasingly fragmented
2. Technology and niche expansion (~3–2 Ma), with the first appearance of lithic technology and animal food processing, as well as features associated with the *Homo* lineage (large brains, reduced dentition, more humanlike body plan)
3. Cognition and cultural processes (~0.5–0 Ma), with the first appearances of “advanced” behavior: depending on definition, this is human seen in humans *or* is common to the Neanderthal and human lineages.

The Evolution of Human Cognition

Evidence for Evolving Cognitive Capacity

Reconstructing the evolution of hominin cognition is fundamentally different to that of other physical features. Thoughts do not fossilize (although their products are occasionally preserved in the archaeological record), but most crucially, the end product – the modern human mind – is more difficult to define than basic anatomy since it is currently not fully understood biochemically nor psychologically. “Cognition” comprises multiple skills and it is possible that these evolved independently, simultaneously, or in a mosaic fashion; but accurate reconstruction of these patterns is difficult. Broader trends in cognitive evolution, however, are clear: as a whole, hominin cognition evolved increasingly

complex functions capable of innovation and abstraction.

This is directly evidenced in increasing brain size, particularly within the *Homo* genus, where both absolute and relative cranial capacities increase exponentially (see Fig. 3). Relative brain size (captured as an allometric relationship between brain and body size in the encephalization quotient [EQ]) is particularly informative about evolving cognition because it suggests “excess” brain presumably used for higher mental processes as opposed to basic functions. Hominin EQs demonstrate a pattern of increasing excess capacity that accelerated during the evolution of *Homo*. This is classically interpreted as evidence of expanding cognitive abilities or intelligence. Beyond broad patterns, elucidating *which* cognitive skills evolved *when* requires finer-grained analysis of where in the brain, specifically, growth occurred. This was long held to be exclusively within the prefrontal cortex, strongly implicating increased social intelligence (Dunbar 1992); but recent reanalyses suggest greater expansion occurred within the cerebellum, implicating fine motor skills (Barton and Venditti 2014).

Evolving cognition is also indirectly captured by its behavioral consequences, which are preserved in the archaeological record. The manufacture of lithic technology is particularly informative because it provides a long and consistent record of change, although other markers of advancing cognition could be used. Two variables – duration of technological tradition and complexity of technology – reflect cognitive states well, but it is important to note that these data are proxies and therefore provide only a scale of the *relative* cognitive abilities of stone tool-producing hominins. Faster turnover of technological traditions and increased complexity within them, manifested in numbers of stone tool “types,” are generally taken as evidence for more advanced cognition; but there are caveats. Stability of tradition is taken as evidence of socially transmitted “culture” in nonhumans, with associated inferences about advanced cognition; and classifying “complexity” within technocomplexes is subjective. In any case, both variables evidence

trends toward advancing cognition over time: technologies change from simple flaked chopping tools to assemblages comprising highly diverse tool types (see section “Technology”), and there is much faster turnover of later technocomplexes, on average, than earlier ones. Within-species change suggests change was not always in the direction of greater complexity, with later Asian *Homo erectus* (s.l.) displaying fewer technological “types” than earlier African forms – although this might reflect the use of alternative local materials like bamboo. The clearest shift toward complexity in both variables occurs with the emergence of *Homo sapiens*, which produced dramatically more variable and rapidly changing technology than all other hominins.

Crucially, when direct and indirect evidence are analyzed together, it becomes clear that markers of cognitive evolution do not change simultaneously. Encephalization is a universal temporal trend in the *Homo* lineage, but this is not directly translated into equal rates of change in technology. This suggests a complex interaction between encephalization, changes in behavior, and evolutionary processes such as speciation. These patterns demonstrate that elements comprising cognition may have evolved independently. The idea of a sudden emergence of “modern” human cognition as a single, unified package comprising culture, language, and consciousness relatively recently is currently not supported by the evidence, and a more cumulative model is more likely.

Social and Ecological Models for the Evolution of Hominin Cognition

What selective pressures and advantages underlay the observed pattern of hominin cognitive evolution? Various ecological and social answers have been proposed. Clutton-Brock and Harvey (1980) examined the relationship between primate brain sizes and relative home ranges, concluding that larger brains are linked to frugivorous diets and larger home ranges. For hominins, whose diets were likely omnivorous and who became increasingly specialized for long-distance ranging in fragmented habitats, this link strongly implies a selective role for sophisticated mental processing

of large amounts of spatial data. In this view, encephalization was thus primarily ecologically functional.

An alternative model is the “social brain hypothesis.” Nicholas Humphrey, Alison Jolly, and Robin Dunbar suggested the problems of living in social environments prompt selection for larger brains. Dunbar (1992) observed a correlation between the relative size of the neocortex and the size of primate social groups. Larger group sizes and associated social complexity thus created selective pressures for bigger, more cognitively advanced brains. This model fits well with the very high levels of social complexity and activity found among humans, with a particularly high degree of social cooperation.

Not all encephalization, however, is found in the neocortex. Recently, Barton and Venditti (2014) demonstrated that the cerebellum, which contains four times more neurons per unit of space than the neocortex, underwent rapid increase during hominin evolution. Consequently, humans have larger cerebella relative to neocortices than other extant primates do. In this “sensory-motor hypothesis,” selection for technical intelligence played a more significant role in cognitive evolution than did social or ecological factors.

These factors, of course, need not be mutually exclusive, and there are clearly interactions between social and ecological factors. Group size, for example, is largely determined by availability and distribution of resources, and equally the size and structure of a group can affect how resources are acquired – for example, hunting among chimpanzees and almost certainly also among hominins.

The Costs of Cognition

Acknowledging evolutionary complexity does not necessarily require the sacrifice of analytical power in favor of untestable description. Falk (1995), for example, does this by making the point that evolutionary models must account for both “prime movers” (major selective agents) and “prime releasers” (changes in physiology that relax constraints on traits, thereby permitting their evolution). “Costs,” in the form of evolutionary tradeoffs between traits, are implicit in the

concept of prime releasers. Explaining how these costs were physiologically mitigated answers the question of *how* cognition evolved, while prime movers explain *why*. The direct costs of evolving cognitive capacity are increased energetic demands. Aiello and Wheeler (1995) suggested these metabolic costs were met, at the individual level, by a redirection of energy from the gut to the brain, necessitating a reduction in the size of the gastrointestinal tract. Falk categorizes these physiological changes, which *permitted* selection for larger brains, as “prime releasers” (1995). Since gut size is strongly determined by diet, Aiello and Wheeler proposed that this reduction was only possible in the context of a shift to higher-quality diets achieved through more complex foraging strategies – that is, smaller quantities of highly digestible food. These shifts in diet and behavior, then, acted as secondary releasers permitting evolving cognition, and to a degree, they exemplify an evolutionary feedback loop, because complex foraging strategies themselves necessitate increased intelligence. Encephalizing brains, however, also entail secondary energetic costs met by relatives. Humans have a prolonged postpartum growth period – childhood – necessitated by limitations on maximum brain size attainable in utero due to the narrow human birth canal. In addition, human infants have 9% greater energetic requirements than similarly sized ape infants due to their encephalized brains (Foley et al. 1991). Life history shifts, like the evolution of a long female postmenopausal lifespan, allowed alloparental investment in offspring to account for some of these energetic costs (Hawkes et al. 1998) and thus acted as tertiary releasers (Fig. 4).

The Evolution of Language

The evolution of language is closely related to that of human cognition. Language both *facilitates* cognitive functions (as internal language, or the language of thought) and their *externalization* (speech). Models of language evolution range from an extremely recent, non-Darwinian emergence in *Homo sapiens* alone to extreme time depth with incremental evolution of its component parts throughout hominin evolution. These contrasting paradigms reflect both differences in

Hominin Evolution, Fig. 4 A model for the evolution of cognition. *Shaded shapes* represent “primary” factors in this model of cognitive evolution, while *clear shapes* represent secondary and tertiary factors – factors produced as consequences of “primary” factors. *Unbroken arrows* indicate the direction of this evolutionary cause-and-effect.

Circles indicate evolutionary constraints, or costs, mitigated by so-called “releasers” (Falk 1995). Accounting for evolutionary costs involves energetic redistributions or life history shifts to account for tradeoffs between traits, and this process is indicated by *dashed arrows*

definitions of language and the paucity of direct evidence.

Elucidating the evolution of human internal language falls far out of the traditional reach of paleo-anthropology (although ingenious attempts have been made), but genetic and anatomical proxies for externalized language suggest at least some form of language in pre-*sapiens* hominins. Neanderthals possessed the derived human version of the speech-related FOXP2 gene (Krause et al. 2007), but its exact role has been debated and its genetic presence alone is insufficient evidence for completely humanlike vocal language. The single Neanderthal hyoid bone from Kebara, Israel, was essentially modern, suggesting a capacity for articulated speech. However, the hyoid provides tentative evidence at best: a modern form is not equivalent to a modern position in the vocal tract. Other attempts to reconstruct speech production by extinct hominins, like analyzing endocast shapes to infer relative sizes of Broca’s and Wernicke’s areas and linking the size of the thoracic vertebral canal to voluntary control of breathing required for speech, have provided highly ambiguous or statistically unsupported conclusions. “Modern”

behavior is linked to both speech and internal language. To the extent that human language is interdependent with symbolic thought, we can infer its existence from “symbolic” artifacts of which the first evidence might extend as far back as shell engravings to 430 kya or a more recent package of evidence for symbolism around the last interglacial (130–70 kya), particularly in Africa. Overall, the evidence suggests language is not the prerogative of modern humans alone; linguistic capacity was likely shared with Neanderthals, also implying a form of language in the LCA they shared. This would place some level of language competence to closer to half a million years ago.

Conclusion

“Our” place in nature is specifically characterized by striding bipedalism; slow life history strategies; large brains capable of complex cognition; human-specific culture based on abstract, symbolic, and internalized thought with a metacognition; articulated language; and an extreme reliance on technology. These traits are related and

interdependent, evolving both in a serial sequence and in parallel, depending on the trait. Fossil, archaeological, and genetic data suggest clear patterns, with bipedalism evolving earlier in human evolution as part of a general shift in ranging and energetics, followed by a technology-based niche expansion. The final period of human evolution was marked by the development of advanced cognition and its behavioral corollaries. However, within each of these phases, there would have been associated coevolution of traits; for example, the coevolution of brain size and changes in life history or diet and technology.

One hundred and 50 years of research into human evolution has revealed much about the tempo and mode of human evolution, showing a complex pattern of novel traits and diversification of lineages, set against a dynamic ecological background. Recent research has been increasingly interdisciplinary, and will continue to be so, with evidence coming from both direct studies of the past – the paleosciences – and inferences from contemporary populations at every level, from the genomic to the cultural.

Homo erectus

Michael Chazan

Department of Anthropology, University of Toronto, Toronto, ON, Canada

Definition

Homo erectus is a species on the hominin lineage that appears in the fossil records approximately 1.8 million years ago. *Homo erectus* is associated with a significant increase in brain size,

developments in stone tool technology, and dispersal out of Africa.

Introduction

The appearance of *Homo erectus* around 1.8 million years ago marks a significant shift in the hominin lineage (the lineage leading to modern humans after the divergence from the chimpanzee lineage). There is debate among paleoanthropologists as to the unity of *Homo erectus* as a species and some choose to designate early African fossils as a separate species *Homo ergaster*. The discovery of five complete skulls at the site of Dmanisi, Georgia demonstrates remarkable anatomical variability within a *Homo erectus* group from a single time horizon leading some paleoanthropologists to identify a series of distinct species (Lordkipanidze et al. 2013). Setting aside debates about the anatomical variability within *Homo erectus*, the fossils attributed to this taxon possess an increased cranial capacity relative to body size in comparison to all preceding members of the hominin lineage (Elton et al. 2001).

Chronology

The first appearance of *Homo erectus* is dated to approximately 1.8 million years ago at sites in South Africa and East Africa (Antón et al. 2014). By approximately 500,000 years ago, populations of *Homo erectus* are replaced by derived taxa trending towards modern humans in Africa and Neanderthals in Europe, although the chronology for the end of *Homo erectus* in Africa remains poorly defined. Based on dates of fossils from Indonesia, it appears that remnant populations of *Homo erectus* might have persisted in East Asia as recently as 50,000 years ago (Swisher et al. 1996).

Behavioral Innovations

There are several major behavioral innovations associated with *Homo erectus*. The development of shaped tools known as handaxes and cleavers

(also called bifaces or large cutting tools) formed by bifacial flake removals begins at about the time of the first appearance of *Homo erectus*. These tools become increasingly refined over time (Chazan 2015). The initial use of fire is dated to ca. one million years ago based on archaeological evidence from Wonderwerk Cave, South Africa, although based on theoretical arguments there is a possibility that already 1.8 million years ago *Homo erectus* habitually used fire for cooking (Berna et al. 2012; Wrangham 2009). *Homo erectus* is associated with an expansion of the hominin range outside of Africa across Europe and Asia. The earliest site outside of Africa is Dmanisi, Georgia, dated to 1.8 million years ago (Ferring et al. 2011). Oddly, the dispersal of *Homo erectus* is not associated with use of handaxes and cleavers and the stone tools found on early sites outside of Africa are restricted to simple flakes and cores. The dispersal of *Homo erectus* provides evidence of the behavioral flexibility of this species and the ability to adapt to novel ecological contexts. However, there is a consistent tendency for archaeological sites associated with *Homo erectus* to be near sources of fresh water.

On archaeological sites, stone tools are often associated with accumulations of faunal remains including the bones of large animals such as elephants. There continues to be debate over the question of whether *Homo erectus* was a hunter or scavenger, although the current data strongly supports the position that *Homo erectus* was a hunter (Domínguez-Rodrigo 2002). One particularly interesting question is what types of weapons *Homo erectus* would have used for hunting as there is no surviving evidence for the use of spears before 500,000 years ago. There is also considerable debate about the role of social learning in *Homo erectus* with most archaeologists agreeing that the production of refined handaxes was a skill transmitted by some degree of learning (McNabb et al. 2004).

Phylogenetic Position

With *Homo erectus* the hominin radiation that saw the diversification of the hominin lineage into

multiple contemporary genera comes to an end and genus *Homo*, represented by a limited number of species, becomes the only surviving genus in the hominin lineage. In a general sense, *Homo erectus* can be considered ancestral to modern humans, Neanderthals, Denisovans, and *Homo floresiensis*, although there is considerable question over whether modern humans and Neanderthals share a common ancestor derived from *Homo erectus*.

Conclusion

With *Homo erectus*, we see a narrowing of the diversity of the hominin lineage to a single genus, genus *Homo*, and the spread of this genus across much of the globe. Reconstructing the cognitive capacity and social organization of this unique and distinctive human ancestor is a key challenge in the study of human evolution. Based on the archaeological record, it is clear that *Homo erectus* was a species capable of both adaptive flexibility and technological innovation.

Definition

Homo floresiensis is a new species of hominin discovered in 2003 during archaeological excavations by an Indonesian-Australian team in Liang Bua cave on the island of Flores, Indonesia. The species is dated to ~90,000 years ago; the presence of an archaic-looking species living at such a recent period is an extraordinary occurrence. This

entry focuses on the discovery, morphology, phylogeny, and controversies surrounding this enigmatic hominin.

Introduction

A series of bones, including a partial skeleton, was discovered in 2003 during an archaeological excavation in Liang Bua cave, on the island of Flores in Indonesia (Brown et al. 2004). The excavation team of Indonesian and Australian researchers was led by the late Professor Mike Morwood and Dr. Tony Djubiantono under the auspices of the Indonesian National Research Centre for Archaeology. The excavation aimed to find insights into the origins of the first Australians but instead the team discovered a number of very different and very small, individuals. The strata in which the remains were found have recently been redated to between 58.3 ± 0.05 and 80.8 ± 0.8 thousand years ago (kya) (Sutikna et al. 2016). This is considerably earlier than the previously reported dates of 13.4–10.2 kya to ~100 kya.

Discovery, Description and Evolutionary Scenarios

The most spectacular find was at a depth of 6 m. It comprised a partial skeleton, labeled LB1, an archaeological reference to the cave in which it was found. These remains include the skull, leg bones, the pelvis, hands, feet, and some other fragments. It was so small that, at first, it was thought that the remains were those of a *Homo erectus* child. But the jaw had a full complement of adult teeth which suggested that, relative to modern humans, this hominin was the equivalent of about a 30-year-old. Although it is not known how death occurred, archaeological evidence shows that the body had not been deliberately buried but, rather, after death, had sunk into mud in a shallow pool of water where it was slowly covered by silt.

There were more than 85 other hominin bones from a number of adult and juvenile individuals

found throughout the 13-m deep excavation. They were all from small individuals. At these levels of the archaeological site there were no bones from individuals with the stature of modern humans.

Brown et al. (2004) compared the Liang Bua remains with those of *Homo erectus*, *Homo ergaster*, *Homo georgicus*, *Homo sapiens*, and *Australopithecus africanus* and found that they showed a mix of archaic and modern characteristics, unlike any other hominin species and was attributed to a new species, *Homo floresiensis*.

The cranium is relatively low with and its widest part at the level of the ears, unlike *Homo sapiens*. Its forehead slopes back from behind a mound of bone that frames the orbits: The jaw lacks a chin (Fig. 1).

Wrists and shoulder joints are quite unlike those of modern humans, and in fact Tocheri et al. (2007) found that the wrists are more like those of African apes and the hands could not open as expansively as ours. As well, Larson et al. (2007) discovered the shoulders face somewhat forward and the arms could not rotate quite as much as ours and, in this, *Homo floresiensis* was more like *Homo ergaster*, which lived 1.5 million years ago in Africa and *H. georgicus*, the 1.8 mya hominins excavated at Dmanisi, Republic of Georgia. Stature is estimated to be just over

Homo floresiensis, Fig. 1 The skull and mandible of Liang Bua 1 (LB1) (Image credit. Debbie Argue)

1 m, and it was a bipedal hominin – it walked upright. Its feet are 70% the length of its shins; in *Homo sapiens* the ratio is 55%. This configuration meant that when walking, these beings had to bend their knees more than modern humans do, just to get ground clearance (Jungers et al. 2009).

It had a small brain in its small skull – 426 cc, similar to the Australopithecines that lived ~4–2 million years ago in Africa. Absolute brain size does not directly measure the cerebral capabilities of an individual; rather, it is the complexity and organization of the brain that is important. Although brains are not usually preserved in ancient fossil remains, sometimes marks on the inside of the skull reveal the presence and form of arteries and of convolutions of the brain. This was the case for LB1. Falk et al. (2005) studied these marks and found that the skull of LB1 had housed a relatively large frontal lobe. In *H. sapiens* this part of the brain is associated with capabilities for planning, for learning from mistakes, and for passing on knowledge from generation to generation. The implication, therefore, is that though *H. floresiensis* was tiny and had a small brain, it probably had some of the same mental abilities as us.

Brown et al. (2004) proposed two possible hypotheses for *H. floresiensis*: (1) that they belong to a new species of small-bodied hominin, *H. floresiensis* that derived from an early lineage of *Homo* and (2) that they represent a new species, *H. floresiensis*, but in this scenario the species derives from an as yet undiscovered early population of immigrant *H. erectus* on Flores that subsequently dwarfed in response to the Island Rule (below). When new skeletal remains comprising a second mandible, a radius, a tibia, and the right humerus and ulna of LB1 were described, however, Morwood et al. (2005) concluded from the new evidence that the ancestors of *H. floresiensis* could **not** be attributed to *H. erectus*. Nevertheless, these two hypotheses continue to be rigorously debated.

Many researchers support the hypothesis that *H. floresiensis* represents a remnant population of a very early member of *Homo*. For example, Falk et al.'s (2005) study of the brain highlighted its archaic characters; Argue et al. (2006) used metric

analyses of hominin crania and showed that *H. floresiensis* sits in with early *Homo* from 1.5 mya in Africa and does not cluster with modern humans; Tocheri et al. (2007) discovered the ape-like characteristics of its wrist bones; Larson et al. (2007) showed that its shoulder bone configuration was last seen on 1.5 mya hominins; Jungers et al. (2009) draw attention to the extraordinary long feet of *H. floresiensis*; and Peter Brown and colleagues undertook a detailed analyses of the two *H. floresiensis* mandibles, in which it is clear that it possesses very archaic characters that do not appear on *H. erectus* (or, indeed, *H. sapiens*). In 2009, Argue and colleagues analyzed and compared the characters of *Homo floresiensis* with those of other *Homo* species – including *H. sapiens* – and some Australopithecines. The analysis showed that *H. floresiensis* probably branched off the human evolutionary tree at a very early stage of the evolution of the genus, *Homo* 1–2 million years after the disappearance of similar hominins from the African continent. They conclude, therefore, *H. floresiensis* is likely to represent a remnant population of a very early hominin on this remote Indonesian island.

The alternative hypothesis is based upon the island rule for insular dwarfing that stipulates that body size of mammals alters when a founder population reaches an island, becomes reproductively separated from its mainland group, and faces an environment different from those of its mainland sister species. For example, a smaller body size would be expected as a response to a limited food supply, a larger size in the absence of predation. In this case, it is assumed that *H. erectus*, known from further west in Indonesia, at Sangiran, arrived on Flores and then, as an evolutionary response to the conditions encountered on Flores, dwarfed. This hypothesis may be tested by analyzing the similarities between the two species. Kaifu et al. (2011) undertook a detailed morphometric and morphological comparison of the LB1 cranium with *H. habilis*, *H. erectus*, and *H. georgicus*. They assessed 67 cranial characters and found that only a few traits support a relationship between *H. floresiensis* and *H. habilis* while 17 characters

supported, or are compatible with, the hypothesis that *H. floresiensis* is an island dwarfed form of *H. erectus* from Java. More recently, Kaifu and colleagues reiterated this hypothesis based upon a comparative study of dentition. There are several other studies in which this hypothesis is supported.

A third hypothesis was proposed almost as soon as the original publication that described the new species came out. Rather than *H. floresiensis* representing an archaic hominin, Henneberg and Thorne (2004) claimed that *H. floresiensis* represents a modern human population with microcephaly. Successive publications have proposed a range of metabolic or genetic disorders in modern humans to explain the morphology of *H. floresiensis*, such as Laron's syndrome, hypothyroid cretinism, and, more recently, Down syndrome. Each of the hypotheses has been fully tested and none has been corroborated. Whether the new dates for *H. floresiensis*, in which an overlap with modern humans on the island is very unlikely, will impact on these hypotheses is too early to say. In any case, the problem with the "pathology" hypotheses is that they do not account for all the facts. Firstly, they are based upon limited aspects of the one skeleton, LB1. But LB1 is not the only individual represented in the Liang Bua cave excavations. The skeletal parts of all other individuals represented are of the same small stature as LB1. Microcephaly and Laron syndrome, and, to a lesser extent, cretinism and even Down Syndrome are rare conditions and one would expect that, even if an archaeological excavation did reveal such a rare skeleton showing evidence of any of these syndromes, most of the skeletal remains would be of a normal, nonpathological population. The *absence* of modern-looking, modern-stature human skeletal material in the deposit is not explained by the proponents of the various pathology-based hypotheses.

Further, the skeletal remains span a long period. The pathology hypotheses fail to explain how a rare condition such as microcephaly or Laron Syndrome could be sustained in *all* known members of a single population for such a long time.

Nor do the pathology hypotheses account for the non-*H. sapiens* mandibular structure, the archaic head shape, archaic facial features, archaic shoulder, and ape-like wrist structure, the relatively short legs in relation to arms, and very long feet on a very short body.

While *H. floresiensis* is known from excavations at only one site, Liang Bua cave, recently a partial mandible and isolated teeth were excavated from Mate Menge in the Soa Basin on Flores. These fossils are dated to ~700,000 years ago – and are therefore more than 600,000 years older than *H. floresiensis*. The new fossils are said to be *H. floresiensis*-like but the researchers await the discovery of more material before they can determine if the remains are indeed *H. floresiensis*.

Conclusion

Homo floresiensis remains a puzzle, and its place on the human evolutionary tree is unresolved. It is not known where these hominins came from; when they first arrived on Flores; or how they got there, given that this island has, it is supposed, never been attached to a mainland. The recent discovery of *H. floresiensis*-like hominins at ~700,000 years ago hints at a long existence of this species and opens up the tantalizing probability that more fossil remains will be discovered on this island.

Definition

Most ancient species of *Homo* found in East Africa between 2.3 and 1.6 million years ago.

Introduction

Based on anatomical similarities between the African apes and humans, Charles Darwin and Thomas Henry Huxley forecast that the oldest fossil evidence for human ancestors would be found in Africa (Huxley 1863). In 1924 Raymond Dart recognized a child's skull from South Africa as a potential ancestral human and named it *Australopithecus africanus* ("southern African ape"). Sometimes referred to as "ape-men," these early hominins were found in abundance at a number of sites in South Africa and were assigned to several distinct species.

After Mary Leakey's discovery of a 1.8 million-year-old cranium at Olduvai Gorge in 1959, field research began to focus more extensively on East Africa and the Great Rift Valley. The cranium, Olduvai Hominid 5 (OH 5), popularly known as "Nutcracker Man," due to its massive molars, was ultimately placed in its own species, *Australopithecus boisei*.

Oddly enough by 1959 much more was known about the anatomy, adaptations, and diversity of the genus *Australopithecus* than of the human genus *Homo* (Latin for man) to which modern humans, *Homo sapiens* (sapient, or wise man), belong. Most scholars were searching outside of Africa for the earliest members of the human genus, and many focused on Europe as the finishing school for modern humans.

Discovery and Anatomy

In 1960 the discovery at Olduvai Gorge of OH 7, a partial mandible containing 13 teeth, much smaller than those of *A. boisei*, was thought to represent a very different kind of early human ancestor from OH 5 (Leakey et al. 1964). Further excavation recovered other fossil bones presumably belonging to the same individual as the lower

jaw. These included hand, wrist, and finger bones, left and right parietal bones (sides of the braincase) of the cranium, an upper molar, and a partial foot. The foot, mandible, and cranial bones exhibited carnivore tooth marks perhaps inflicted by a hyena responsible for the death of this individual.

This fragmentary, juvenile skeleton, also dated to 1.8 million years, indicated the presence of a second kind of hominin at Olduvai Gorge. Discovered by the Leakey's eldest son, Jonathan, the find was dubbed "Johnny's Child." In 1964 Louis Leakey, Phillip Tobias, and John Napier published a new species, *Homo habilis*, in the journal *Nature* (Leakey et al. 1964). The species name meaning "handy man" was suggested by Raymond Dart, making reference to Oldowan stone tools found nearby likely made by this early human.

Oldowan tools include scrapers, choppers, spheroids, and proto-hand axes made by simple stone on stone percussion. The raw material, predominately quartz, was obtained from a source area several kilometers away from the lakeside where they were utilized to butcher meat that was scavenged from carnivore kills. The oldest Oldowan tools date back to 2.6 mya (million years ago), but there are no associated hominin remains.

Features such as the reconstructed cranial capacity for *H. habilis* of approximately 674 cc (roughly three cups of coffee) as well as the slender anatomy of the mandible and the narrow, elongated molars all pointed in the direction of *Homo* and not *Australopithecus*. Compared with *A. africanus* from South Africa, the cranial capacity for "Johnny's Child" was some 50% greater justifying its placement in the genus *Homo*.

Controversy and Further Finds

This new species was widely contested by other paleoanthropologists, but further remains of *H. habilis* fossils from Olduvai Gorge added legitimacy to this new taxon as a valid species. These included OH 24, an adult, crushed, female cranium, referred to as "Twiggy," OH 13, a female upper and lower jaw associated with cranial fragments, nicknamed "Cinderella," and OH 16, a

fairly complete male cranium, lacking a face, was dubbed "George." *H. habilis* was an upright walking, early member of our genus, *Homo*, with a cranial capacity greater than *Australopithecus* and with hands capable of stone tool making, bearing jaws and teeth reduced in size and gracility compared to *Australopithecus*. Fossils assigned to this species have been found in Kenya, Ethiopia, and perhaps South Africa, but there is continued debate as to which of these finds are identical to *H. habilis* (Tobias 1991) as defined at Olduvai or constitute or another species of *Homo* (Wood 2014).

While the definition of *H. habilis* rests on cranio-dental features, little was known about the postcranial anatomy (below the neck) until the 1986 discovery by the Institute of Human Origins team from Arizona State University, Tempe, Arizona, of a partial skeleton, OH 62, of this species (Johanson et al. 1987). This specimen eroded from 1.8 million-year-old strata where some 302 fragments were recovered.

Parts of a right arm, humerus (upper arm), two forearm bones, radius and ulna, a fragmentary left femur (thigh bone), and a scrap of right tibia (shin bone) were recovered as well as associated splintered fragments of teeth, small shards of cranium, and fortunately a partial maxilla, the upper jaw. Reconstructed from 32 fragments, the maxilla held the key to the species identification of the skeleton. Not only did the maxilla resemble other *H. habilis* finds at Olduvai Gorge in anatomy and size but it also lacked the megadont teeth so characteristic of *A. boisei*.

The recovery of OH 62 constitutes the first time upper and lower limb bones of *H. habilis* were securely associated. This presumably female individual was relatively elderly as inferred from the heavily worn adult teeth. Estimated to be approximately a meter tall (39 inches), OH 62 is the smallest ancient hominin ever recovered, suggesting that the larger *H. habilis* at Olduvai Gorge such as OH 7 were probably males, indicating a large degree of size difference between males and females, a condition referred to as sexual dimorphism.

Although fragmentary, the humerus and femur afforded estimated lengths used in calculating a

ratio of upper arm and lower thigh bones. In chimpanzees, quadrupeds, the humerus is 100% the length of the femur indicating that fore and hind limbs are used in locomotion. In modern humans, the humerus is only about 70% of the length of the thigh, a biomechanical arrangement reflecting our dependence on bipedal locomotion. Surprisingly in OH 62 the humerus is 95 per cent the length of the femur, similar to the condition seen in *A. afarensis*, the ‘Lucy’ skeleton. The implication is that evolutionary change toward modernity first centered on the cranio-facial region and only later on the postcranial skeleton.

Reconsideration of *Homo habilis*

In 2015 a state-of-the-art computer reconstruction of the original OH 7 mandible and cranium has thrown new light on the anatomical nature of this type specimen for *H. habilis* (Spoor et al. 2015). The mandible was severely distorted as a result of lateral forces during fossilization resulting in a significant distortion of the shape of the dental arcade. After mirror-imaging the undistorted left half of the mandibular dental arcade and correcting for a damaged area along the midline, the correct shape of the dental arcade could be reconstructed. Surprisingly the dental arch was not rounded, as is the case in modern humans, but exhibited relatively long, parallel tooth rows, reminiscent of *Australopithecus*.

A computer visualization of the cranial bones of OH 7 also revealed something surprising in that the cranial capacity for this specimen was significantly underestimated. Previous cranial capacity calculations centered around 674 cubic centimeters, but the new estimates suggested a much higher value around 729–824 cubic centimeters, falling within the range of *Homo erectus*, known from Java and elsewhere.

Conclusion

The mixture of more advanced features like an enlarged brain and more ancient features such as a

long, parallel sided dental arch in OH 7 has significant implications for the placement of *H. habilis* on the human family tree. The more rounded, human-like dental of a 2.3 million-year-old maxilla, upper jaw, from the site of Hadar, Ethiopia, would not have articulated with the reconstructed OH 7 mandible. This suggests that prior to 2.3 mya, the *Homo* lineage had already split into two lineages implying that *H. habilis* from Olduvai Gorge is not necessarily the progenitor to later species of *Homo* as previously proposed.

The recovery of a 2.8 million-year-old partial mandible at Ledi-Geraru, Ethiopia, exhibits a mandibular anatomy and a dentition that places it comfortably within *Homo* (Villmoare et al. 2015). Other anatomical features of the jaw suggest evolutionary affinities with older *Australopithecus afarensis* mandibles. This suggests that Lucy’s species, *A. afarensis*, that disappears around 3 mya, should be considered the ancestor to the *Homo* lineage (Johanson 2017).

Definition

Archaic *Homo* found in Europe, Africa, and possibly Asia between 70,000–200,000 years ago.

Introduction

In 1907 a heavily built mandible, containing a complete set of teeth, was discovered by workers at a sandpit just outside of Heidelberg, Germany, in a village called Mauer. Initial observations of the jaw suggested similarities with *Homo neanderthalensis*, but the combination of a massive mandible and quite small teeth suggested something different. Paleontologist Otto Schoetensack gave a new species name to the fossil, *Homo heidelbergensis* (Heidelberg Man) (Schoetensack 1908). It has been a challenge to determine a precise geological date for this middle Pleistocene mandible considered to have lived sometime between 475,000 and 700,000 years ago.

Unfortunately, no cranial remains were found at Mauer, but a number of skulls from other sites in Europe, Africa, and, perhaps, China, dating to the same geological epoch as the Mauer mandible, are referred to *H. heidelbergensis*. The best preserved European specimens were found at Petralona, Greece, and Arago, France (Harvati 2007; Rightmire 1998).

Additional Finds

Comparative anatomical study of skulls from Petralona and Arago led to the conclusion that the Mauer mandible would have been a good fit for these skulls, and therefore they should be placed in *Homo heidelbergensis* (Harvati et al. 2010). It has been difficult to geologically date the Petralona skull which was found in 1960 by shepherds in a cave close to Thessalonika, but associated animal bones provide an estimate of 350,000 years. The rugged male skull has a cranial capacity of 1220 cc and a massive supraorbital torus resembling other skulls (see below) that have been assigned to *Homo heidelbergensis*. Analysis of the anatomy of the Petralona specimen confirms a mosaic of primitive (*Homo erectus* like) and Neanderthal anatomy.

In 1971 a 400,000-year-old skull, Arago XXI, was excavated in the eastern Pyrenees in a limestone cave located near Tautavel, France. Initial impressions of the heavily built skull, presumably a male, with strong brow ridges and a low cranial capacity of 1166 cc suggested that it might belong to a primitive species well known in Asia called *Homo erectus*. More comprehensive analysis of Arago reveals many resemblances with the Petralona specimen and is now placed in *Homo heidelbergensis*. This decision is supported by the recovery of mandibles at Arago that resemble the Mauer mandible.

African Finds

In Africa the most complete crania assigned to *H. heidelbergensis* come from Bodo, Ethiopia, and Kabwe, Zambia. The Zambian cranium, found by workers at the Broken Hill Mine in what was then called Rhodesia, is sometimes referred to as Rhodesian Man or the Broken Hill skull (Smith-Woodward 1921). Today it is known as the Kabwe skull. No stone tools were recovered, but associated parts of a pelvis and lower limb provide a glimpse into the postcranial skeleton, suggesting that Kabwe was a very tall and robustly built male.

The Kabwe skull has a cranial capacity of 1325 cc and was incredibly massive, sporting a prominent supraorbital torus at the front of the cranium. The majority of the dentition exhibits very heavy wear, with cavities and root abscesses that must have been painful. An undiagnosed lesion on the left wall of the cranium, above the ear canal, may also indicate disease.

Debate on Naming

Considerable debate has swirled around placement of all these specimens in a single species, *Homo heidelbergensis*, a taxon that was based on a single mandible. However, the European and African crania share many details of morphology and are collectively considered to be the kind of skull that would have had a Mauer-like mandible. Found in 1921 the cranium from Kabwe was given a separate species name, *Homo rhodesiensis*, leading some anthropologists to retain that name for the African material (Stringer 2012).

The Bodo skull was found in 1976 in Middle Awash Valley, Ethiopia (Conroy et al. 1978). Hand axes and cleavers made on lava, of the Acheulean industry, were found nearby, and the associated faunal remains suggested a Middle Pleistocene age. The geological age of the Bodo specimen was confirmed with argon dating to be 600,000 years old.

The powerfully built Bodo skull with a very thick, projecting supraorbital torus possesses the largest face in the human fossil record and a cranial capacity of 1250 cc. Upon close examination, numerous cut marks were found on the cheeks, in the eye orbits, and on the frontal bone, indicating intentional defleshing of this individual (White 1986).

Sima de los Huesos

More than 5000 human fossils were excavated at Sima de los Huesos (“Pit of Bones”) located in the Atapuerca Mountains of northern Spain (Arsuaga et al. 2014). These bones come from the Middle

Pleistocene epoch and have been dated to 400,000 before the present. Initially these fossils were placed in *Homo heidelbergensis*, because of anatomical similarity to other skulls placed in *Homo heidelbergensis*. Some anthropologists also drew attention to many anatomical resemblances of the Sima de los Huesos bones shared with *Homo neanderthalensis*. The amalgam of older *Homo heidelbergensis* anatomy with later, derived Neanderthal features has attracted widespread debate. Perhaps it is useful to view Neanderthals within the accretion model that posits the gradual accumulation of Neanderthal features over time. With the recovery of diagnostic Neanderthal DNA in Sima de los Huesos bones (Matthias et al. 2016), a plausible interpretation is that they represent an early stage in the Neanderthal lineage that led to later “Classic Neanderthals.”

Conclusion

It is now widely agreed that the great number of anatomical similarities shared by all *Homo heidelbergensis* fossils justifies their inclusion in a single species. In Europe, as a result of their isolation due to Pleistocene glaciations, they evolved into Neanderthals. The African fossil record for *Homo heidelbergensis* such as Bodo and Kabwe supports an African origin for modern humans who migrated into Europe and replaced the Neanderthals.

Definition

Archaic *Homo* found in Eurasia between 400,000 and 40,000 years ago.

Introduction

Although Neanderthal fossils were first recovered in Belgium in 1830 and in Gibraltar in 1848, it

was not until 1856 when skeletal remains found by miners in the Feldhofer Cave in the Neander Valley, Germany, that scientists entertained the idea that the bones might belong to an extinct form of an ancient human (Shreeve 1995). In 1864, the bones were assigned to the species *Homo neanderthalensis* (Neander Valley Man). This was the first recognition of an extinct human relative. At that time, the prevailing view considered Neanderthals as an extinct kind of human that played no role in the ancestry to modern humans. In the 1930s several scholars challenged this interpretation and entertained the view that Neanderthals were progenitors to modern humans. Today Neanderthals are seen as an evolutionary lineage close to modern humans that exchanged some genes with us but died out roughly 40,000 years ago.

Geographical Distribution and Geological Age

Numerous Neanderthal remains have been found from Great Britain to Spain and eastward to the Middle East and Uzbekistan; no Neanderthal fossils have ever been recovered from Africa. Neanderthal DNA can be traced back to roughly 400,000 years ago in fossil bones from the Atapuerca Mountains at Sima de los Huesos in northern Spain, tracing the roots of Neanderthals much deeper in time than anticipated (Meyer et al. 2016). Carbon 14 dating places Neanderthal extinction at approximately 40,000 years before the present, shortly after the migration of modern humans, *Homo sapiens*, into Europe (Wood et al. 2013).

Neanderthals evolved as a single lineage in Eurasia and appear not to have spawned any other descendants. The most ancient Neanderthals exhibited incipient skull anatomy that gradually became more distinctively Neanderthal over time due to natural selection and genetic drift as they continued to be isolated in a glacial Europe. By 50,000 years ago *H. neanderthalensis* evolved its full blown “Classic Neanderthal” morphology both in the craniofacial region and throughout their postcranial skeleton. Examples of the later

Neanderthals include some well-known finds such as those from La Chapelle-aux-Saints in France and Amud in Israel.

Neanderthal Anatomy

Neanderthal faces are characterized by a heavy, double-arched, supraorbital brow behind which are enlarged frontal sinuses. The nasal aperture is broad and large with an expanded nasal cavity bordered by big maxillary sinuses. The middle face juts forward, a feature called midfacial prognathism, and gives the impression that the entire nasal region was pulled forward. The cheek bones, immediately below the orbits, slope backward unlike in modern humans where this region presents a flat face where our prominent cheeks define a right angle below the orbit (Harvati 2015).

The distinctive Neanderthal craniofacial morphology is interpreted largely as a response to the glacial and periglacial environments in Eurasia where they lived. A large nasal opening and nasal cavity functioned to warm and humidify the cold, dry glacial air. The large sinuses functioned much like double pane windows as insulators to keep the brain from becoming chilled.

Neanderthal brain cases were long and low from front to back and sported a substantial “chignon” or projecting bun at the rear of the skull. The average Neanderthal brain measured 1520 cc (cubic centimeters) and ranged in size from 1200 cc to as much as 1700 cc. Modern human brains average around 1400 cc, and the larger Neanderthal average probably reflects the additional endocranial space required to house an increased blood flow to keep the brain warm.

Generally Neanderthal teeth fall in the size range of modern humans, but molars are distinct in having large pulp cavities, a condition known as taurodontism. However, the anterior teeth are large and exhibit heavy wear as if they are used perhaps in some activity like chewing hides. The mandible lacks a chin, and in lateral view a large space (retromolar gap), maybe associated with midfacial prognathism, is evident immediately behind the wisdom tooth (third molar).

Neanderthal bodies are short in stature, stocky, and heavily built with strong, thick-walled bones. Relatively speaking the lower leg and forearm bones are shortened compared to modern humans. The short, stocky bodies, and abbreviated limb segments undoubtedly reflect an adaptation to the cold environment of glacial Europe. Thus with a reduced skin area to body mass ratio their bodies served as heat conservers. In contrast modern human bodies, especially in tropical regions, are tall and slender with long limbs, thus increasing the ratio of skin area to body mass enhancing heat dissipation allowing for cooling of the body.

Neanderthal Behavior

Neanderthals led stressful lives in Arctic-like environments under rugged conditions as is seen in frequent evidence of trauma, perhaps brought about during close encounter hunting episodes employing thrusting spears. Bone fractures occur in both male and female individuals implying that both sexes participated in hunting. Studies of the age of death suggest that Neanderthals did not have long life spans. A number of Neanderthal skeletons show healed fractures, possibly a reflection of some level of compassion and care by other individuals.

Archaeological evidence suggests that Neanderthals did not lead culturally sophisticated lives (Marean 2005). The stone tool technology traditionally associated with Neanderthals, known as the Mousterian, was named after the site of Le Moustier in the Dordogne region of France. The tools of this Middle Paleolithic period consisted of stone flakes that were modified into points, scrapers, and even small hand axes. Employing a knapping technique known as the Levallois, a number of smaller flakes are first removed from a larger stone core. This prepares the core that is then struck with a single percussive blow, fabricating a large disc-like flake. Tools were fashioned exclusively on stone unlike the more recent Upper Paleolithic technology, brought into Europe by *Homo sapiens*, where bone, antler, and ivory served as a source for

making tools and carvings. While there are minor regional differences in the shapes of flake tools throughout the geographic distribution of the Mousterian, the extensive variation in Upper Paleolithic blade technology reflects a significantly more sophisticated cultural diversity associated with *Homo sapiens*.

Faunal remains recovered from excavations of Neanderthal living sites indicate that they were principally carnivorous eating large amounts of meat from a variety of mammals such as the aurochs, horse, deer, and bison, as well as wild boar and ibex. Neanderthals living closer to the Mediterranean Sea included marine mammals and even shellfish in their diet (Stiner 2006). Studies of stable isotopes recovered from Neanderthal skeletons, like nitrogen and carbon, confirm a diet dominated by large, cold adapted herbivores such as woolly rhinos and woolly elephants (Richards and Trinkaus 2009).

The lack of art associated with Neanderthals, with some minor exceptions such as an engraved figure, similar to a hash mark found on the floor of a Gibraltar cave in strata containing characteristic Mousterian artifacts, suggests that Neanderthals were not capable of symbolic thought. Neanderthals must have had some level of communication, but it is unlikely they possessed symbolic language that is one of the defining hallmarks of *Homo sapiens*.

Neanderthals occasionally buried their dead, but their graves show a paucity of ritual grave goods in characteristic of later *Homo sapiens* interments. Discovery of crayons of variously colored ochre and even manganese suggest that Neanderthals may have practiced some degree of self-adornment.

An abundance of eagle, falcon, and vulture wing bones recovered from a number of Neanderthal sites implies that feathers were intentionally collected and worn as ornamentation. Cut marks and polishing on eagle talons recovered from a Neanderthal site in Croatia and Italy imply that these were worn as jewelry (Peresani et al. 2011). Discoveries such as these are beginning to paint a somewhat more “humanlike” view of Neanderthals in contrast to the long-prevailing view that they were dim-witted brutes.

Neanderthal Extinction

Not everyone agrees as to why Neanderthals went extinct 40,000 years ago, but they vanished only a few thousand years after modern humans arrived from Africa. The Upper Paleolithic industry associated and brought in by *Homo sapiens* is significantly more advanced and varied than the Mousterian. In the Upper Paleolithic, sophisticated techniques were employed to make blade tools, tools with long cutting edges like knives. Blade tool technology is a more efficient use of stone than Mousterian flake technology. *Homo sapiens* used spear throwers, also known as atlatls, and perhaps also the bow and arrow, both of which greatly enhanced their hunting prowess compared to Neanderthals that killed by jabbing spears in dangerous close encounter episodes. Neanderthals were unable to compete with these technologically advanced peoples who may even have used dogs during hunting (Shipman 2015). Polychrome paintings on cave walls and exquisitely carved mobiliary art objects further attest to the cognitive superiority of the modern humans over Neanderthals.

Neanderthal and Modern Human Interbreeding

Migrating out of Africa, modern humans may also have brought with them pathogens against which Neanderthals had no immunity. Paleogenetic studies confirm that moderns and Neanderthals interbred, opening up the possibility that tropical infectious diseases could have been a factor in Neanderthal extinction.

It is clear that the Neanderthal lineage went extinct and *Homo sapiens* prevailed, but genetic analysis confirms that our direct ancestors and Neanderthals did interbreed with humans, perhaps during three separate time periods, before their extinction (Green et al. 2010). Both Neanderthal mitochondrial DNA and a complete nuclear genome of Neanderthals have now been sequenced and compared with modern humans. Modern Eurasians have inherited between 1 and 3% from Neanderthals.

In this early stage of paleogenetics, understanding the function of the genes we inherited from Neanderthals is difficult, but it is certain that some of these genes were beneficial and other are deleterious to humans (Gibbons 2016). For example, it appears that some archaic genes actually conferred an increased immune response in modern humans. While other genes may not have been so beneficial and may have contributed to depression, the risk of nicotine addiction, increased risk of blood clots, and even urinary infections.

According to the biological species definition, different, even closely related species should not be capable of interbreeding and exchanging genes. However, in the case of *Homo neanderthalensis* and *Homo sapiens*, these two species were similar enough to have experienced some level of interbreeding. No fossils retaining intermediate hybrid morphology have been recovered. Although a 24,000-year-old subadult skeleton from Lagar Velho, Portugal, was thought to be a Neanderthal-human hybrid, unlikely since Neanderthals had already been extinct for 16,000 years. The Lagar Velho find may be a modern *Homo sapiens*, with cold adapted features in its postcranial skeleton as in Eskimos.

Conclusion

Current thinking views Neanderthals as a separate, successful, and geologically long-lived Eurasian lineage of humans that were morphologically and behaviorally distinct from anatomically and behaviorally modern humans, *Homo sapiens*. And while Neanderthals did interbreed with us and contributed some favorable genes to *Homo sapiens*, as a lineage, they went extinct.

Definition

Homo rudolfensis is a species of early *Homo* that is known from ~1.8 million years ago in East Africa. Despite more than 40 years of research and analyses, it is still unclear where this hominin sits on the human evolutionary tree.

Introduction

Fossil hominin bones found in Kenya in 1973 remain enigmatic despite 43 years of discussion and analysis. The bones comprise a partial cranium and face and leg bones. The cranium and face have the Kenya National Museum name KNM-ER 1470. Just where they fit on the human evolutionary tree has long occupied researchers, but a resolution has not been forthcoming, and it is unclear as to what other fossils might belong in the same species as KNM-ER 1470.

History of Discovery and Taxonomic Challenges

In 1973 Mr. Bernard Ngeneo discovered a relatively intact cranium in the East Rudolf area of Kenya during fieldwork led by Mr. Richard Leakey. The cranium is known by its museum reference KNM-ER 1470 (Kenya National Museums-East Rudolf). Possibly associated postcranial bones were also found – a right femur (KNM-ER 1472), discovered by Dr. J. Harris; part of a second right femur (KNM-ER 1475; discovered by Mr. Kamoya Kimeu); and skeletal material (KNM-ER 1481; Dr. J. Harris) (Leakey 1973).

The brain case and partial facial skeleton were found in deposits under a volcanic tuff that was at that time dated to 2.6 mya. We now know that the skull is from deposits dated to 1.8 million years ago (Mcdougall et al. 2012) and are thus contemporaneous with cranium KNM-ER 1813 *H. habilis* (East Africa) that was at the time the earliest member of our genus.

At the time of discovery the taxonomic status of the remains was not clear. Not only did KNM-ER 1470 differ from fossil hominins known at the time, it also had an unexpected mix of Australopithecine and *Homo* characters. The size and form of the cranium suggested that it should be included within the genus *Homo*, but the flat fronted, wide palate, and form of the supraorbital region are suggestive of the Australopithecines; and the postcranial (femora – leg bones) cannot be distinguished from *Homo sapiens*. Leakey (1973) therefore attributed the fossils to *Homo* sp. indet (Fig. 1).

Since its discovery, opinions have differed about the species into which this cranium should be placed. In a joint publication Alan Walker and Richard Leakey “agreed to disagree,” Walker preferring to place KNM-ER 1470 in *Australopithecus* and Leakey would place it to *Homo* (Walker and Leakey 1978, p. 54). The challenge facing us is the unexpected mix of characters in the specimen. It has a domed calvarium with steeply sloping sides that have parietal eminences; the frontal (forehead) rises relatively steeply (but not as greatly as modern humans), which are

Homo rudolfensis, Fig. 1 *Homo rudolfensis* cranium KNM-ER 1470 (Image credit: Debbie Argue)

characteristics of *Homo*. But the size and flatness of the face and the shallow, broad, and short palate are reminiscent of *Australopithecus*, although the wide palate in relation to its length differs from the shape of the *Australopithecine* palates (Leakey 1973). Its cranial capacity is 752 cc while *Australopithecines*' cranial volume range from 387 to 560 (Holloway et al. 2004).

Because KNM-ER 1470 existed at the same time and in the same general region as *H. habilis* it became customary to include KNM-ER 1470 in that species, although Groves (1985, p. 264) notes that there was never any attempt to justify this assumption. The differences in the cranial capacities and general morphology of KNM-ER 1470 and crania attributed to *H. habilis*, however, led some researchers to suggest that the fossils might better be assigned to two species, while others attributed these differences to sexual dimorphism within *H. habilis*.

The first to separate the species into two was Groves and Mazak (1975) who attributed a mandible KNM-ER 992, at the time included *H. habilis*, to a new species, *H. ergaster*. Wood (1985) showed that the KNM-ER 1470 parietal bone is within the *H. erectus* range in some aspects but different in others and that the base of KNM-ER 1470 is metrically similar to *H. erectus* (OH 9, KNM-ER 3733 and 3883). He, therefore, asks, in relation to KNM-ER 1470 and *H. habilis* KNM-ER 1813 "Are we dealing with one taxon, or two?" (Wood 1985, p. 211). Using statistical methods applied to expected cranial capacities in a population, he finds that the chance of the two crania being from the one population is <5% and that KNM-ER 1470 and KNM-ER 1813 should not be uncritically regarded as being sampled from the same taxon (Wood 1985). He concludes that even more tantalizing than the differences between KNM-ER 1470 and KNM-ER 1813 is the possibility that not two but three species existed in the East Africa in the Early Pleistocene: *H. habilis*, *H. erectus*, and a taxon that included KNM-ER 1470.

Questioning the coexistence of more than one species of *Homo* in the human evolutionary journey occurred in an intellectual milieu that viewed the evolution of *Homo* as unilineal. That is, until

the question of KNM-ER 1470 was raised it was thought that *H. sapiens* evolved from *H. erectus* that evolved from *H. habilis*. To maintain this paradigm, any variation around any of these species was considered a "grade." In this context, Groves (1989) tested the unilineal concept of human evolution by applying cladistic analysis to the *Australopithecines* and *Homo*. His cladograms consistently returned results in which KNM-ER 1470 was on a separate branch to other species in the analyses, *H. habilis* and *H. erectus*. He attributed KNM-ER 1470 to a new species, *Homo rudolfensis* (Alexeev 1986). This species name is a derivative from Alexeev (1986), who, 3 years earlier, had attributed KNM-ER 1470 to *Pithecanthropus rudolfensis*. Under the rules of taxonomic nomenclature the name first published in accordance with the rules is the correct name for a taxon so, in this case, *rudolfensis*, is retained, but the genus name is amended, and the originator of the name is appended. The unique characters that distinguish *H. rudolfensis* are the flat form of the zygomatic root, lack of internal buttressing of the mandible, and some morphologies of the premolars (Groves 1989: 264).

Those that would retain KNM-ER 1470 in *H. habilis* regard the species as being highly sexually dimorphic, regarding the larger KNM-ER 1470 as a male of the species and the smaller crania as females (such as KNM-ER 1813 that has a cranial capacity of 509 cc; Holloway et al. (2004)). In this case, the species name *H. habilis sensu lato* is used in the literature, and *H. habilis sensu stricto* is applied if the researcher includes only the smaller crania in *H. habilis*.

A further challenge within this somewhat complicated situation is the lack of agreement as to the composition of *H. rudolfensis*. For example, William Kimbel and colleagues include KNM-ER 1470, KNM-ER 1590, KNM-ER 3732 *H. rudolfensis*; David Strait and colleagues' sample comprised 9 fossils; Lee Berger and colleagues included 11 fossils in their compilation of *H. rudolfensis*; David Lordkipanidze and colleagues include KNM-ER 1470, KNM-ER 62000, and OH65 in the species; while other studies limit the species to KNM-ER 1470.

H. rudolfensis, then, is somewhat of an enigma. Where does it fit on the human evolutionary tree? What is it most closely related to? In 2001, Leakey et al. (2001) announced a new hominin genus and species discovered in East Africa, *Kenyanthropus platyops* sp. nov. The species comprises a largely complete cranium KNM-WT 40000 and part of an upper left jaw and face KNM-WT 38350. The former has an estimated age of 3.5 mya; the latter has an estimated age of 3.3 mya. Leakey et al. (2001) draw attention to the similarity of KNM-WT 40000 to KNM-ER 1470, *H. rudolfensis*. Both have a flat face, a vertically oriented cheek region, lack of a supraorbital sulcus, and an anterior origin for the root of the zygomatic arch. The main differences between the KNM-ER 1470 and *K. platyops* cranium KNM-WT 40000 relates to the more primitive nasal characteristics of KNM-WT 40000 and the higher cranial vault (larger braincase) of KNM-ER 1470 (Leakey et al. 2001). Cameron (2003) sees similarities among *Kenyanthropus* and *H. rudolfensis* in the pattern of growth stages in brain morphology and cranial and dental development that differed from *Paranthropus*. He suggested *Kenyanthropus* and *H. rudolfensis* may form a sister group relationship to the exclusion of *Paranthropus*. This led him to propose that *K. platyops* was the ancestor of *H. rudolfensis* and the species should be renamed *Kenyanthropus rudolfensis*. So it seemed that at last that the ancestor of *H. rudolfensis* had been identified, but others have questioned this and a possible phylogenetic relationship between *Kenyanthropus* and *H. rudolfensis* needs further clarification.

Conclusion

Just what *H. rudolfensis* is, where it sits on the human evolutionary tree, and even the tantalizing prospect that its ancestors may have been discovered are unresolved questions despite more than 40 years of comprehensive research. Is there hope for a resolution? Yes, probably. In the last 15 years, a remarkable suite of

discoveries of new hominins has been made, so there is more comparative material with which to compare *H. rudolfensis*, and, judging by the recent increase in the rate of new fossil discoveries, there is every chance that more *H. rudolfensis* fossils will be found that will fill out our understanding of its morphology so that we can better assess its place on the human evolutionary tree.

Definition

Generally, homophobia refers to prejudice, stereotyping, and/or discrimination based on sexual orientation – particularly directed by heterosexuals

toward lesbian, gay, and bisexual individuals (hereafter referred to as LGB). *Prejudice* refers to the specific emotional reaction to a person because of one's sexual orientation. *Stereotypes* refer to the beliefs about others due to classifying them according to their sexual orientation, and *stereotyping* refers to the process of applying stereotypes of a certain sexual orientation group to an individual member of that group. *Discrimination* refers to differential behavior toward an individual as a function of their sexual orientation.

Introduction

Homophobia is a term often used to describe prejudice and discrimination directed toward non-heterosexual individuals. As the name implies, the concept *homophobia* denotes a fear-based response toward those who are attracted to and/or engage in sexual behavior with members of the same sex. While still used colloquially, researchers more often employ the term *sexual prejudice* to refer more generally to prejudices directed toward members of a particular sexual orientation group, especially toward lesbian, gay, or bisexual individuals (LGB). Researchers only recently considered prejudices against LGB individuals as part of the prejudice and intergroup relations research, which historically focused primarily on interracial and interethnic prejudices. As such, research on sexual prejudice derives from only a few theoretical perspectives (e.g., focusing largely on gender role violations and threats to sexual identity), and just recently have researchers begun applying an evolutionary perspective to understand the range of sexual prejudices. This entry provides a summary of the existing research on sexual prejudice in light of an evolutionary analysis.

Using Evolutionary Psychology to Understand (Sexual) Prejudice

How can evolutionary psychology explain stereotypes about, prejudices toward, and discrimination based on sexual orientation? Human

cognition, emotion, and behavior evolved to effectively manage recurring threats and opportunities to survival and reproduction, including those posed by other people (i.e., affordances). Throughout evolutionary history, humans faced a consistent set of challenges to survival and reproduction, including successfully mating and raising children, avoiding disease and danger, and successfully navigating the social terrain provided by group living (Kenrick et al. 2010). Successful cognitive, emotional, and behavioral responses to these challenges and opportunities increased the likelihood of an individual's survival and reproduction, which, through differential reproduction over time, led to evolved psychological mechanisms for addressing these recurring challenges and opportunities.

Evolutionary approaches to inter- and intra-group relations argue that (1) humans evolved as social, group-living animals, (2) effective group functioning requires psychological processes facilitating group functioning, and (3) evolution shaped mechanisms to manage threats and opportunities of group living (Cottrell and Neuberg 2005). This affordance management perspective contends that inter- and intra-group prejudices stem from perceived threats attributed to outgroups and perceived threats to ingroup functioning (e.g., threats to health, physical safety, sexual autonomy, socialization). Stereotypes, as socially transmitted information about others, convey threat and opportunity-relevant information. Likewise, specific affective emotional responses to perceived stereotypes characterize the prejudices underlying inter- and intra-group dynamics. These perceptions and emotional reactions facilitate specific behaviors designed to respond effectively to the perceived threats and opportunities attributed to specific ingroup and outgroup members, thus characterizing discrimination based on social group identity.

This functionally driven, affordance-based perspective on intergroup dynamics and prejudice allows researchers to predict specific emotional and behavioral tendencies based on the threats associated with stereotypes of different groups. For example, threats to physical and sexual autonomy elicit fear, avoidance, and escape. Threats to

health elicit physical disgust, avoidance of the contaminant, and if contaminated, expulsion of the contaminant via cleansing or aggression. Moral transgressions elicit moral disgust, aggression, and suppression or expulsion of the moral violator. Obstacles to desired outcomes elicit anger and aggression to remove the obstacle. Mating, parenting, and social affiliation opportunities (i.e., positive affordances) elicit positive emotions (e.g., lust, love, compassion) and approach behaviors to facilitate successful mating, parenting, and affiliating. This entry combines the affordance management approach to prejudice with the fundamental motives theory to demonstrate how perceptions of threats to fundamental human motivations elicit affective prejudices and behavioral responses to respond to the perceived threats.

Overview of Stereotypes of, Prejudices Toward, and Discrimination Against LGB

This entry summarizes and interprets the existing sexual prejudice research through the lens of an evolutionary, threat-based framework. Specifically, it examines how the perception of threats to fundamental human motives (e.g., disease threats, parenting and childrearing threats, values threats, status threats, and mating autonomy threats) engage emotional and behavioral reactions to effectively manage these threats.

Disease threats. Relative to a variety of other social groups (e.g., European Americans, African Americans), gay men are perceived as more likely to pose threats to physical health (Cottrell and Neuberg 2005). This perception of threats to health predicts increased disgust and negativity toward gay men (relative to other social groups; Cottrell and Neuberg 2005), and individual differences in general disgust predict greater negative attitudes toward gay men (and lesbians, albeit using a measure confounding attitudes toward gay men with attitudes toward lesbians; Terrizzi et al. 2009). In addition, activating concern for disease increases sexual prejudices and contamination-avoidant behaviors specific to gay men. Specifically, activating disease concern by

exposing people to a disgusting odor (relative to no odor) decreased warmth toward gay men but not lesbians, heterosexuals, or other social groups unassociated with disease (Inbar et al. 2012). Further, imagining an interaction with a gay man (vs. heterosexual man) increased heterosexuals' desire for physical cleansing, measured by greater activation of words associated with physical cleanliness, greater liking of cleansing products, and greater likelihood of selecting a sanitary wipe over a pencil as compensation (de Zavala et al. 2014).

Parenting and childrearing threats. Heterosexuals believe that gay men and lesbians (relative to heterosexuals) are more likely to influence children's gender and sexual orientation development by making them more likely to become non-heterosexual (Filip-Crawford 2015) and therefore decreasing one's inclusive fitness by proxy. Parenting enhances these stereotype-based concerns about children's safety. Comparing parents to nonparents in a random sample of adults, parents reported greater levels of sexual prejudice (using scales measuring a myriad of negative beliefs against "homosexuals"), even after controlling for sex, number of nonheterosexual friends, religiosity, education, and age (Gallup 1995). College students who simply imagined having children reported similar prejudices – heterosexual college students rated their distress to a scenario depicting their (imagined) 8- or 21-year old child spending the night at a friend's house (the friend's parent was gay and either the same or opposite-sex to the child); participants reported the greatest distress to the scenario involving a young child staying with a same-sex gay parent (Gallup 1995).

Experimentally activating parenting concerns increases sexual prejudices. Activating traditional family roles (i.e., viewing a photo of a traditional family vs. a photo of a garden) caused participants to judge a gay father more negatively across a series of traits than a heterosexual father (Vescio and Biernat 2003). Further, activating the importance of family values (i.e., writing about the importance of family/friends vs. the importance of one's sense of humor) increased sexual prejudice toward gay men and lesbians (i.e., a measure assessing a myriad of beliefs about gay men and

lesbians), as mediated by increased endorsement of traditional husband-wife family values (Lehmiller et al. 2010).

These prejudices map onto behaviors designed to keep LGB men and women away from children. Specifically, heterosexuals report increased discomfort with "homosexuals" participating in roles and occupations in which they interact closely with children and could potentially socialize them to be gender or sexual orientation non-normative or have intimate contact with children – roles as teachers, school bus drivers, and doctors (especially pediatricians), but not auto mechanics, bank tellers, airline pilots, construction workers, lawyers, or sales clerks, relative to a control condition with the sexual orientation unspecified (Gallup 1995).

Values threats. Relative to other social groups (e.g., European Americans, welfare recipients, heterosexuals), LGB individuals are often perceived as more likely to hold nontraditional values that potentially undermine and violate traditional values based on parenting, romantic relationships, gender roles, and religion (e.g., Brambilla and Butz 2013; Cottrell and Neuberg 2005; Haddock et al. 1993; Henry and Reyna 2007; Pirlott and Neuberg 2014). For example, homosexual behavior directly defies many explicit religious teachings and values – all three of the Abrahamic religions (which represent a large proportion of the world's religions) explicitly prohibit homosexuality. Perhaps unsurprisingly, a meta-analysis of measures of religiosity and sexual prejudice revealed associations of religiosity and greater levels of sexual prejudice (Whitley 2009). Specifically, more frequent religious attendance, greater levels of religiosity, greater levels of fundamentalism (belief that one set of religious teachings exist which contain absolute truths which must be followed absolutely), greater levels of Christian orthodoxy (agreement with core beliefs of Christianity), and greater intrinsic religiosity (internalizing religious teachings) predicted greater prejudices toward gay men and lesbians (Whitley 2009). Extrinsic religiosity (using religion to achieve nonreligious goals; e.g., socializing) was unrelated to sexual prejudice, and quest religiosity (using religion as a search for

existential meaning) predicated greater tolerance toward gay men and lesbians (Whitley 2009).

Such perceived threats to traditional values predict elevated prejudices toward LGB. Perceived threats to sexual morality predicted elevated negative attitudes toward gay men and lesbians (Crawford et al. 2014). Perceived threats to ingroup values predicted disgust toward gay men (Cottrell and Neuberg 2005). Finally, manipulating normative gender role behavior affects sexual prejudice; for example, heterosexual men reported greater dislike for feminine male targets more than masculine targets (Blashill and Powlishta 2009).

Experimentally activating traditional values and threats to ingroup values elicits prejudices against LGB. For example, priming a general symbolic values threat (reading an editorial commenting on the worsening of values and traditions in participants' home country) suppressed warmth toward gay men relative to nonsymbolic threat (editorial about climate change) and non-threat conditions (Brambilla and Butz 2013). Subliminally activating Christianity (using Christian words relative to neutral words) increased coldness toward gay men relative to heterosexual men (Johnson et al. 2012). As previously mentioned, activating the importance of traditional family values increased sexual prejudice toward gay men and lesbians, driven by elevated endorsement of traditional husband-wife family values (Lehmiller et al. 2010). Finally, both the situational activation of and individual differences in endorsement of traditional family values (as discussed above) predicted harsher evaluation of a gay father relative to a straight father (Vescio and Biernat 2003).

Perceived threats to heterosexual values predict the endorsement of aggression and aggressive behavioral responses against LGB. For example, perceptions that gay men and lesbians violate traditional values related to relationships, sexual morality, religion, and family predicted opposition to same-sex marriage and adoption rights (Henry and Reyna 2007; Reyna et al. 2014). Priming a symbolic values threat suppressed support for gay rights relative to nonsymbolic threat and nonthreat conditions (as previously discussed;

Brambilla and Butz 2013). In addition, a large body of research suggests that aggression against LGB may stem from perceived gender role violations, particularly violations performed by men (e.g., Gordon and Meyer 2007). Finally, research examining reasons why college students verbally or physically aggressed against a gay person identified a religious and moral values threat component – i.e., “because of my religious beliefs” and “because of my moral beliefs” (Franklin 2000).

LGB values are also perceived as “transmittable” – i.e., that pro-gay ideologies are contagious and that interacting with a gay man or lesbian increases a person's support for gay rights (Filip-Crawford 2015). Further, the degree of “contagiousness” of gay behavior and pro-gay ideology also depends upon community structure, as a particular individual's social influence is stronger in more tightly knit social communities. Perceptions of greater community connectedness predicted greater aggressive intentions toward gay men and lesbians (Filip-Crawford 2015). Filip-Crawford (2015) also manipulated social community connectedness by telling college students that the university social scene is either highly or loosely connected and asked students to write about a time consistent with this. Highly connected communities increased highly prejudiced participants' intentions to aggress and increased actual behavioral aggression (noise blasts) against gay men and lesbians relative to weakly connected communities.

Threats to status via stigma by association. Simply interacting with another person potentially causes others to characterize one as similar to their companion, despite salient differences, especially if the target's companion belongs to a stigmatized group. This phenomenon is known as *stigma by association* – the process by which associating with members of a stigmatized group similarly stigmatizes “normal” individuals (Neuberg et al. 1994). Associating with LGB individuals can stigmatize heterosexuals as gay, therefore, affecting their social status and mating potential. For example, highly prejudiced heterosexual men assumed a man (with an unspecified sexual orientation) who voluntarily chose a gay roommate was

as likely to be gay as a man specified as gay and more likely to be gay than a man with a heterosexual roommate (Sigelman et al. 1991).

Why might the labeling of a heterosexual as gay upset heterosexuals? Mislabeling heterosexuals as gay can reduce future mating opportunities if opposite-sex potential mates are no longer interested in mating with the stigmatized individual, and thus can have reproductive costs. In addition to mating costs, stigmatization as nonheterosexual can have the same social ostracism costs as those afforded to LGB individuals. For example, persons interacting with an LGB individual experience similar discrimination as LGB men and women: Heterosexual men display increased negativity toward another man seen interacting with a gay man – they feel less comfortable interacting with the stigmatized man, rate him as less social and civil, and even socially distance themselves from him by rating themselves as less similar – than when he was interacting with a heterosexual man (Neuberg et al. 1994).

Heterosexuals are often aware of the potential stigmatization from interacting with LGB men and women (Buck et al. 2013), and the anticipation of stigma by association threatens from associating with LGB men and women predicts anxiety toward LGB individuals (Buck et al. 2013). This anticipation of stigmatization also predicts both physical and psychological avoidance of same-sex gay/lesbian individuals. For example, stigma by association concerns predicts an increased desire to avoid interacting with a same-sex gay/lesbian person (Plant et al. 2014) or roommate (Buck et al. 2013). Buck et al. (2013) induced threats of stigma by association by randomly assigning heterosexual participants to create an LGB-supportive poster and either sign their name (stigma by association condition) or not (control), which elicited public avoidance of LGB people as assessed by refusal to sign a petition for LGBT rights. Swim et al. (1999) examined women's use of social distancing to avoid stigma by association. Women participated in a panel comprised of two male confederates and one female confederate; the female was either a lesbian or presumably heterosexual. Each panel member publicly reported their preferences to a

series of questions, and whether the participant's response was different from the female confederate indicated public social distancing. Highly prejudiced women's responses more frequently differed from the female confederate posing as lesbian than as heterosexual, suggesting they used social distance to avoid stigma by association.

Threats to mating autonomy. Perceived unwanted sexual interest from certain sexual orientation targets concerns many heterosexual individuals. For example, when asked to imagine a negative interaction with a gay man, the most prevalent scenario generated by heterosexual men involved unwanted sexual interest (42% of scenarios generated; McDonald et al. 2014). Furthermore, a primary concern reflected in heterosexual women's stereotypes about lesbians is that lesbians seduce heterosexual women (Eliason et al. 1992).

Pirlott and Neuberg (2014) measured perceptions of unwanted sexual interest by asking heterosexual college students to rate their own sexual interests toward heterosexual, bisexual, and gay/lesbian male and female targets as well as their perception of each of these groups' general sexual interest in heterosexual people of their same sex. They calculated sexual interest discrepancies by subtracting the perceivers' own sexual interests in the target group from their perceptions of the target groups' sexual interests in heterosexuals of their same sex, for each group. Heterosexual women perceived bisexual men, bisexual women, and lesbians to pose threats of unwanted sexual interest, yet not heterosexual men (mutual sexual interest targets) or gay men and heterosexual women (mutual disinterest targets). Heterosexual men perceived threats of unwanted sexual interest from gay and bisexual men but not from heterosexual men (mutual sexual disinterest targets) or from heterosexual and bisexual women (mutual sexual interest targets) or lesbians (unreciprocated sexual interest targets).

Perceptions of unwanted sexual interest map onto prejudices toward certain sexual orientation targets. Pirlott and Neuberg (2014) found that heterosexual female participants expressed more negativity toward bisexual men, bisexual women,

and lesbians (unwanted sexual interest targets) relative to heterosexuals and gay men (mutual sexual interest/disinterest targets). Heterosexual male participants also expressed more negativity toward gay and bisexual men (unwanted sexual interest targets) relative to heterosexuals, bisexual women, and lesbians (mutual sexual interest/disinterest targets), and perceptions of unwanted sexual interest mediated the relationship between sexual orientation groups and general negativity (Pirlott and Neuberg 2014). Further research demonstrates that heterosexuals avoid same-sex gay/lesbian individuals, particularly in potentially intimate situations. Imagining a same-sex gay/lesbian roommate increased likelihood of private avoidance of that roommate relative to a heterosexual roommate (Plant et al. 2014), which could serve to minimize threats of unwanted mating.

Conclusion

Stereotypes, prejudices, and discrimination against LGB individuals are not *evolved*, *per se*. The human social psychology of cognition, emotion, and behavior, however, evolved in response to recurrent threats to and opportunities for survival and reproduction. Consistent recurrent threats to physical safety, sexual autonomy, health, ingroup functioning and group living, parenting, and mating, for example, exerted significant selection pressures on humans to evolve a threat management system (Schaller and Neuberg 2012) to detect and respond effectively to perceived threats and opportunities in the environment, including those posed by other people.

Accordingly, although the stereotypes, prejudices, and discriminatory behaviors against LGB individuals are not evolved, the perception of and affective and behavioral responses to the threats (and opportunities) attributed to LGB individuals are evolved. As discussed above, heterosexuals believe certain LGB men and women pose threats to health, child socialization, ingroup norms and values, status via stigma by association, and sexual autonomy via unwanted sexual interest. The stereotypes of LGB individuals convey perceived

threat and opportunity affordances, which elicit specific affective and behavioral reactions to functionally respond to these affordances, as predicted by evolutionary theory. Perceived threats to health predict elevated disgust toward gay men and contamination-avoidant and cleansing behavior (Cottrell and Neuberg 2005; de Zavala et al. 2014). Perceived threats to child socialization predict elevated prejudices and sequestering children from LGB individuals (Filip-Crawford 2015; Gallup 1995; Henry and Reyna 2007; Lehmiller et al. 2010; Reyna et al. 2014; Vescio and Biernat 2003). Perceived threats to ingroup norms and values predict increased negative prejudices, disgust, and aggression against LGB individuals, as a way to prevent the social influence and block counter-normative behaviors of LGB individuals (Blashill and Powlisha 2009; Brambilla and Butz 2013; Cottrell and Neuberg 2005; Crawford et al. 2014; Franklin 2000; Filip-Crawford 2015; Gordon and Meyer 2007; Lehmiller et al. 2010; Vescio and Biernat 2003). Perceived threats undermining social status (e.g., appearing gender nonnormative or non-heterosexual) via stigma by association predict anxiety and public avoidance of LGB individuals to minimize potential stigmatization (Buck et al. 2013; Plant et al. 2014; Swim et al. 1999). Perceived threats to sexual autonomy predict elevated negativity and desires to avoid these individuals in potentially intimate situations to minimize the risk of unwanted sexual activity (Pirlott and Neuberg 2014; Plant et al. 2014).

In conclusion, although the research exploring prejudice toward nonheterosexuals (i.e., homophobia or sexual prejudice) is somewhat recent and less extensive than research on race- or ethnicity-based prejudices, this does not undermine the evolutionary underpinnings of the stereotypes, prejudices, and discriminatory behavioral responses toward LGB individuals. Stereotypes relevant to prejudices and discrimination reflect perceived threats to survival and reproduction. These perceived threats engage affective and behavioral responses designed to mitigate these threats. This functional set of cognitive, affective, and behavioral responses arise reliably from evolved mechanisms. Using an evolutionary

approach to examine LGB prejudices and inter- and intra-group dynamics more broadly provides a powerful framework for truly understanding human behavior.

Definition

Experiences of harassment or discrimination on the basis of actual or perceived sexual minority status.

Introduction

Lesbian, gay, and bisexual (LGB) youth show a number of health disparities relative to heterosexual youth, including greater psychological distress, suicidality, sexual risk behaviors, and substance use (Kann et al. 2016; Saewyc 2011). Similar patterns have been identified for transgender youth, although less is known about this population due to the lack of items to identify transgender respondents in population-level surveys (Reisner et al. 2016). A substantial body of research has linked these disparities with experiences of homophobic bullying and victimization (e.g., Collier et al. 2013; Kosciw et al. 2014). Homophobic bullying can take a variety of forms (e.g., verbal harassment, physical assault) and is experienced differentially by subgroups of LGBT youth. School climate also plays an important role in shaping LGBT youths' experiences of homophobic bullying, and supportive resources can promote resilience among LGBT youth.

Prevalence of Homophobic Bullying

Homophobic bullying can take a variety of forms. A nationwide survey of lesbian, gay, bisexual, and transgender (LGBT) students conducted by the Gay, Lesbian, and Straight Education Network (GLSEN) in 2013 examined some of the most common forms, including hearing biased language (e.g., "That's so gay") and anti-LGB remarks (experienced by 71% of LGBT youth in the past year), verbal harassment (e.g., name-calling or verbal threats, experienced by 74% of LGBT youth in the past year), physical harassment (e.g., pushing or shoving, experienced by 36% of LGBT youth in the past year), physical assault (e.g., being punched, kicked, or injured with a weapon, experienced by 17% of LGBT youth in the past year), and cyberbullying (e.g., verbally harassing or anti-LGB text messages or social media posts, experienced by 49% of LGBT youth in the past year). A more recent population-level survey found similar patterns: LGBT youth reported higher prevalence rates of bullying on school property, electronic bullying, feeling

unsafe at school, and a number of other violence indicators relative to heterosexual youth (Kann et al. 2016). Although peers were the most common perpetrators of homophobic bullying, 51% of LGBT youth reported hearing teachers or school staff making homophobic remarks (Kosciw et al. 2014). Encouragingly, the GLSEN survey also found that experiences of homophobic victimization are declining over time as social attitudes about sexual minorities change (Kosciw et al. 2014). This may reflect the links scholars have drawn between homophobic bullying, societal attitudes, and broader relationships to structures of power (Payne and Smith 2013).

Demographic Differences in Homophobic Bullying

Although LGBT youth experience higher levels of homophobic bullying than heterosexual youth, research also documents variation between subgroups of LGBT youth. Youth who are questioning their sexual orientation experienced higher homophobic teasing and peer victimization than LGB or heterosexual youth (Birkett et al. 2009). Bisexual youth and youth who report both male and female sex partners, particularly boys, reported more fighting, skipping school due to feeling unsafe, property theft, or damaged than lesbian, gay, or heterosexual youth (Russell et al. 2014). LGBT youth of color experienced greater victimization than white LGBT youth. Also, middle school students experienced greater victimization than LGBT high school students (Kosciw et al. 2014). Middle school appears to be a period of elevated developmental risk, as LGBT middle school students reported lower access to supportive resources, lower school belongingness, and higher truancy than high school students (Kosciw et al. 2014; Robinson and Espelage 2011). There is also evidence that although more overt forms of homophobic bullying decline across development, more indirect forms persist into adolescence (Russell et al. 2014). Homophobic bullying may also be experienced by children of LGBT parents (Clarke et al. 2004; Kosciw and Diaz 2008), and additional research is needed to understand the experiences of these students.

Students in different educational contexts also reported different prevalence rates of homophobic bullying. LGBT students in public schools reported higher victimization than students in private or religious schools (Kosciw et al. 2014). LGBT students in rural or small town schools reported higher victimization and fewer supportive resources than students in urban schools (Kosciw et al. 2014). Across the United States, LGBT students in the South and Midwest reported higher levels of homophobic victimization than LGBT students in the Northeast and South; LGBT students in the South also reported fewer supportive resources than students in other regions (Kosciw et al. 2014).

In addition to experiences of victimization on the basis of sexual orientation, youth may experience bullying on the basis of actual or perceived gender minority status. Transgender youth experience a range of forms of bullying on the basis of gender expression (Kosciw et al. 2014). Additionally, violation of gender norms may drive many instances of bullying for both sexual and gender minority students (Payne and Smith 2013). Research is needed to better understand the experiences of transgender students and to examine how homophobic bullying and bullying on the basis of gender identity and expression may intersect and overlap.

Impact of Homophobic Bullying

Homophobic bullying has been linked with a number of adverse outcomes for LGBT youth, including psychological well-being, attendance and academic achievement, and educational aspirations and future plans. In terms of psychological well-being, it has been associated with greater depression, traumatic stress, alcohol and substance use, and suicidality as well as lower self-esteem (Collier et al. 2013; Kosciw et al. 2014). In terms of school attendance and academic achievement, LGBT youth who experienced high levels of past-year victimization had lower grade point averages (GPAs) and were three times more likely to miss school in the past month than youth with low levels of past-year victimization (Kosciw et al. 2014). Other research has found that homophobic bullying is associated with higher truancy

and lower school belonging (Collier et al. 2013) and that feeling unsafe in school mediated the relationship between identifying as a sexual minority and experiencing higher truancy and lower grades (Birkett et al. 2014). In terms of educational aspirations and future plans, LGBT youth who experienced high levels of past-year victimization were twice as likely to report not planning to pursue post-secondary education than LGBT youth with lower levels of past-year victimization (Kosciw et al. 2014). As homophobic bullying impacts both short-term (e.g., attendance and achievement) and long-term (e.g., educational aspirations and future plans) academic outcomes, it likely leads to disruptions in LGBT youth's educational trajectories (Collier et al. 2013).

Although it is important to understand how experiences of homophobic bullying lead to negative outcomes for LGBT youth, it is also important to highlight that many LGBT youth demonstrate resilience despite these experiences. In fact, most sexual minority youth thrive and achieve health and well-being similar to heterosexual youth, despite greater experiences of adversity and risk factors (Saewyc 2011). To understand these processes of resilience, research is needed that attends to contextual factors, particularly protective factors. Research on school climate has provided important contributions in this area.

Homophobic Bullying and School Climate

School climate is important to understanding homophobic bullying, as school climate has been found to moderate the relationship between homophobic bullying and negative psychological outcomes (with students in more positive school climates experiencing fewer negative outcomes; Espelage and Swearer 2008; Hatzenbuehler et al. 2014). Similarly, school-based supportive resources are associated with lower victimization and better academic outcomes for LGBT students (Kosciw et al. 2013). Incorporating a focus on school climate is consistent with a social-ecological approach, which underscores the role that risk and protective factors play on multiple levels (e.g., families, schools, communities, societies) in shaping the impact of bullying on LGBT

youth (Hong and Garbarino 2012; Hong and Espelage 2012).

In addition to moderating the impact of homophobic bullying on psychological and academic outcomes, school climate may play an important role in shaping responses to homophobic bullying. Most LGBT students (57%) who experienced harassment or assault in school did not report this experience, primarily because they doubted this would result in effective intervention. This perception appears to be founded, as most LGBT students who did report the experience (61%) said that school staff did nothing in response (Kosciw et al. 2014). More effective school responses to homophobic bullying are an important area of future growth to foster more positive school climates and more positive outcomes for LGBT youth.

Similar to demographic differences in experiences of homophobic bullying, demographic differences in perceptions of school climate have been found. Transgender youth report the most hostile school climates of all sexual and gender minority groups (Kosciw et al. 2014). In terms of sexual orientation, questioning students report a less positive school climate than LGB or heterosexual youth. Both school climate and homophobic teasing moderated the relationship between sexual orientation and depression, substance use, and truancy, with questioning youth who reported more negative school climates or higher levels of homophobic teasing most likely to report negative outcomes (Birkett et al. 2009).

Several kinds of resources that contribute to a more positive school climate for LGBT students have been identified, including anti-bullying policies, gay-straight alliances (GSAs), and other LGBT-related student organizations, inclusive curricula, and supportive school personnel (Hatzenbuehler et al. 2014; Kosciw et al. 2014). The most recent GLSEN School Climate Survey found that LGBT youth have reported an increase in all of these forms of support over time (Kosciw et al. 2014). In terms of anti-bullying policies, most LGBT students (82%) reported their school had an anti-bullying policy; however, only a small minority (10%) reported the presence of a comprehensive policy that included sexual orientation

and gender identity (Kosciw et al. 2014). In terms of GSAs and student organizations, half of LGBT students reported the presence of a GSA or similar organization in their school. Those students who reported the presence of such a student organization reported higher levels of school connectedness and lower levels of homophobic bullying (Kosciw et al. 2014). Other research has found that students in these schools also reported improved mental health and lower harassment (Saewyc 2011). In terms of inclusive curricula, a minority of students reported being taught positive representations of LGBT people or history (19%), and almost as many (15%) reported being taught negative representations (Kosciw et al. 2014). Additionally, curricula that do address LGBT people or issues may do so only in superficial, limited, or problematic ways, such as through onetime events or representations that reinforce pathological representations of LGBT people (Payne and Smith 2013). Finally, in terms of supportive school personnel, almost all LGBT youth (96%) could identify at least one supportive school staff member; however, less than two-thirds (61%) could identify at least six (Kosciw et al. 2014). Supportive school personnel are an especially important resource, as support networks are important buffers of the impact of homophobic bullying on LGBT youth (Espelage and Swearer 2008).

Conclusion

LGBT youth report a range of forms of homophobic bullying, including antigay remarks, verbal and physical harassment, and cyberbullying. Some subgroups are especially at risk for homophobic bullying, including LGBT youth of color, questioning and transgender youth, and middle school students. School climate plays an important moderating role, with students in more positive school climates reporting more positive health outcomes. A number of factors contribute to more positive school climate, including anti-bullying policies, LGBT-related student organizations, inclusive curricula, and supportive school personnel.

Courtship displays, mounting and/or genital contact, and stimulation between same-sex individuals.

Introduction

Various authors use different definitions of homosexual behavior. The one used is after Sommer and Vasey (2006). Bagemihl (1999) characterizes homosexual behavior in terms of courtship, affection, interactions involving mounting and genital contact, pair bonding, and parenting activities between same-sex individuals. More recently, Poiani (2010) defines homosexual behavior as an interaction that is sexual or of sexual origin and that is performed between two or more individuals of the same sex. He distinguished homosexual behavior from homosexuality, which is a sexual orientation characterized by sexual attraction to individuals of the same sex.

Homosexual Behaviour

Homosexual behavior either in males or females is common and widespread among social

nonhuman species (Bagemihl 1999; Poiani 2010; Sommer and Vasey 2006). It is rarely associated with sexual orientation, however. Domestic sheep *Ovis aries* is so far the only mammalian species where spontaneous sexual orientation of up to 10% of rams to other males has been repeatedly reported (Perkins and Fitzgerald 1992). The proximate causes of same-sex preferences may be induced by specific situations. Steroids and other hormones, genetic and epigenetic mechanisms modified by stress during prenatal or perinatal period have been shown to have potential to induce homosexuality mainly, but not only, in mammalian males (Balthazart 2016). Also, early postnatal social environment such as removal of other sex from the rearing environment that affected sexual orientation in some mammals and birds has been reported (Poiani 2010).

In most of the cases, animal homosexual behavior is not associated with sexual orientation and the animals involved may and do reproduce. There are numerous situations when depriving individuals of members of the opposite sex causes them to engage in sexual interactions with members of the same sex. Though, when the deprivation is ceased, such formerly deprived animals immediately renew regular heterosexual behavior (Bailey and Zuk 2009). Still, most of the cases of homosexual behavior in animals are not primarily associated with clear sexual context. Understanding social relations requires correct interpretation of the significance of such behavior. While male-male mounting is a common behavior, female-female mounting is also widespread. For some farm ungulates, intra-female mounting has been understood to be a normal element of behavior associated with estrous aimed to signal to males the female is ready to mate. However, observations of female-female mounting outside the rut have been frequently reported as well. Female bonobos, *Pan paniscus*, for example, embrace frequently each other ventroventrally and rub their genital swellings against each other (Hohmann and Fruth 2000). Hohmann and Fruth (2000) observed bonobo females and investigated five hypotheses on the function of this behavior. During 5-year-lasting study, they found support for multifunctional origin of the behavior, most of

all to reconciliation and social tension regulation. They concluded that genital contacts may express quality and dynamics of dyadic social relationships among female bonobos. Similar function can also be seen in many other primate species where homosexual behavior also often promotes alliance formation between sexual partners.

Same-sex mounting in socio-sexual context has been classically suggested to signal dominance. It was first suggested for primates, but later also for many other taxa. When reviewing literature, there are a number of papers supporting dominance signaling hypothesis. On the other hand, many other reports are not consistent with the view that actors are dominant and recipients subordinate (short review in Bartoš and Holečková 2006). The dominant individuals mount subordinates, solicit mounting by subordinate conspecifics, or prevent subordinate to mount them. Opposition against being mounted may but need not occur. As a result, there is a wide variation between as well as within species in who is mounting whom and how the mounted individual responds. Thus, who mounts whom may, in fact, reflect decision of the dominant individual involved rather than signaling the dominance per se.

What is misleading with dominance signaling hypothesis is that even when a dominant male mounts subordinate one, male-male mounting can be associated with penile erection, occasionally anal intromission, and ejaculation. In this context, erection has been regarded as indicative of sexual arousal and thus evidence of a sexual motivation underlying same-sex mounting (Bagemihl 1999). Moreover, mounting is apparently testosterone dependent, because bulls mounted others more frequently than steers, male-male mounting of fallow deer bucks was associated with the start of a seasonal increase in testosterone levels following seasonal minima (Bartoš and Holečková 2006), and testosterone treatment of cows increased their mounting behavior (Bouissou 1978). Here it should be emphasized that there is also a lot of obviously nonsexual situations such as serious fighting associated with penile erections (e.g., Bartoš and Holečková 2006). This seeming

contradiction may most likely lie in a mix-up of motivations. For example, androgens, testosterone in particular, in males shape and modify sexual as well as agonistic behavior (Michael and Zumpe 1993). Therefore, it frequently happens that some elements of behavior typical for sexual behavior can occur in agonistic context and vice versa regardless if such a behavior was functional or even dangerous. Moreover, it is also known that disturbance and tension associated with a stressful situation can be linked to mounting. Thus, penile erections, anal intromission, and ejaculation during male-male mounting cannot be taken as real evidence of sexual motivation. Rather, it might be attributed to excitement associated with serious fighting (Bartoš and Holečková 2006).

Conclusion

In conclusion, same-sex orientation in non-human animals is extremely rare. In contrast, same-sex sexual behavior is quite common. It does not seem to have any special, exclusive function. In particular, it cannot be clearly linked to roles of a dominant actor and subordinate recipient. Instead, intra-sex behavior is likely to be a consequence of deprivation from the other sex or a side effect of excitement, not necessarily sexual. Hence, depending on circumstances, various proximate factors and ultimate functions may be involved.

Definition

The heritable components of human homosexuality are not immediately explicable according to basic evolutionary principles because they entail reduced average individual reproductive success relative to alternative genotypes.

Introduction

Evolutionary psychology generates research questions by considering the ancestral survival and reproductive challenges faced by humans and human ancestors. At the heart of evolutionary thinking is reproductive success, as every trait informed by genetics must allow for its own replication in the next generation. For example, a genetic mutation that causes early death or sterility will not replicate under normal circumstances and is thus quickly removed from the population. Less extreme cases of limited reproductive success also tend to be outcompeted by prevailing alternatives. If a mutation merely reduces fertility (i.e., lower probability of fertilization at each copulation, all else equal), one may expect it to be outcompeted by alternatives and exit the gene pool after some number of generations. Homosexuality appears to be a trait that, like sterility or reduced fertility, reduces the likelihood of reproduction. One can think of exclusive homosexuality as analogous to sterility and non-exclusive homosexuality as analogous to reduced fertility. This has led researchers to wonder how homosexuality continues to appear at a relatively consistent rate in the human population. Strictly speaking, a paradox is an inconsistent or logically contradictory premise; the maintenance of homosexuality is better described as a puzzle or a mystery, since a solution exists, even if it is not forthcoming. Before looking at how researchers have responded to this puzzle, it is necessary to consider whether it is appropriate to apply evolutionary thinking to homosexuality in the first place.

Williams (1966) encouraged evolutionary thinkers to avoid invoking evolutionary theory whenever simpler mechanisms are sufficient in explaining a phenomenon. If the expression of

homosexuality is not influenced by genetics or other heritable elements, then evolution will not help explain its existence. If the expression of homosexuality is not common or culturally universal, then evolution may be unnecessary to explain its existence. Likewise, if the expression of homosexuality is not an ancestral human condition, evolutionary theory may be unnecessary. Finally, if the expression of homosexuality does not reduce reproductive success relative to alternatives, then it is not fundamentally mysterious according to evolutionary theory. Evidence regarding each of these conditions is discussed ahead.

Does Homosexuality Have Heritable Components?

Heritability estimates (h^2) describe the proportion of phenotypic variance that is attributable to genetic relatedness. These estimates are calculated by looking at the probability of expressing a particular phenotype (in this case, homosexual identification) as a function of genetic relatedness to others who express that phenotype (in this case, homosexual relatives), compared to the probability of expressing the phenotype in the general population. In other words, a trait is heritable to the extent that it is more likely to reoccur within families than between unrelated people. Especially useful for these estimates is data on identical twins who were reared apart and thus did not also share identical developmental environments. Depending on the methods and statistical assumptions used, twin studies provide heritability estimates between roughly $h^2 = 0.3$ and 0.6 for men and $h^2 = 0.2$ and 0.7 for women (e.g., Alanko et al. 2010). These are considered moderate to large estimates for psychological variables; personality variables cluster around $h^2 = 0.5$ and intelligence is between $h^2 = 0.5$ and 0.8 . As long as a trait is heritable, it can be subject to natural selection; thus, it is irrelevant in this context where the genes that contribute to homosexuality are located or what they do. That said, one popular hypothesis for males is that differences in genes on the X chromosome of mother and child cause developmental feminization of male brain

regions involved in sexual behavior (Mustanski et al. 2005). No specific genetic hypotheses are available for females, although prenatal androgen exposure appears to be important.

Is Homosexuality Universal and Frequent?

Rates of homosexual identification vary by region, but anthropological studies in every region of the world find homosexual expression of some description. These expressions can differ wildly. Egalitarian homosexuality is the predominant form in modern Western societies, wherein two adult, gender-typical individuals enter into short- and long-term sexual relationships. However, transgendered forms of homosexuality, wherein homosexuals adopt opposite-sex gender roles and appearance from a young age, have also been well documented in populations like the *fa'afafine* of Samoa, the *hijra* of India, the *kathoey* of Thailand, and the *berdache* of Native America. Some researchers argue that transgendered homosexuality represents the more ancestral form of male homosexual expression, as evidenced by its preponderance in societies with more ancestral cultural practices (VanderLaan et al. 2013). Others argue that the oldest and most widespread form of male homosexual behavior is transgenerational, wherein young men become sexual apprentices to older men until they reach maturity. This form of male homosexual behavior is likely distinct from male homosexuality as a preference for same-aged male partners but has been documented as a common and socially sanctioned practice in cultures ranging from Ancient Greece and Rome; to the Azande and Zulu tribes; to India, Pakistan, and Persia; to Imperial China, Japan, and Korea; to Melanesia, Polynesia, and aboriginal Australia (Greenberg 1988).

Unfortunately, female homosexuality is less well documented by anthropological and historical sources, partly because in many cultures no terminology was developed to define female homosexuality and (relatedly) because female homosexuality has been marginalized by male historical perspectives that disbelieve or discredit female homosexual preferences. Despite these

limitations, female homosexuality is understood to be universal and diverse. Native American women frequently inhabited a similar transgendered homosexual role as homosexual men. For example, the *hwame* of the Mohave possessed unique spiritual faculties, and their marriage to women was viewed as normative (Blackwood 1984). Similar practices are observed in many African societies in Nigeria and Kenya, where women may take on the role of husband and father. Women in Lesotho are known to develop intimate sexual friendships with other women in which they engage in the full range of sexual acts but do not consider their acts sexual because no penis is present. In the West and elsewhere, female homosexuality is expressed in long- and short-term relationships, and females who practice homosexual behaviors range from highly masculine to highly feminine and everything in between.

Like heritability estimates, global rates of homosexuality are imprecise as a result of differences in methods and populations. The best estimates for the number of men who identify as homosexual are between 2 % and 5 %, although somewhere between 5 % and 15 % of men report some attraction or sexual behaviors toward the same sex (e.g., Bagley and Tremblay 1998). Between 1 % and 3 % of women identify as homosexual, although somewhere between 10 % and 15 % report some attraction or sexual behaviors toward the same sex (Mercer et al. 2007). Non-heterosexual women are more likely to report being bisexual or queer, whereas non-heterosexual men are more likely to report being exclusively homosexual. This has led to the suggestion that females experience greater “sexual fluidity” than males (Diamond 2009). Regardless, rates of both male and female homosexuality are greater than would be expected to be the result of random mutation, and the breadth of cultures in which homosexuality is found recommends that it is not the result of particular environments.

Does Homosexuality Reduce Reproductive Success?

Western male homosexual identification is associated with roughly a third the number of

offspring that are had by heterosexual males. Males who identify as homosexual are much more likely than heterosexual males to never have offspring, and when they do, they tend to have fewer across the life span (Schwartz et al. 2010). Data on females suggests that homosexuality is associated with about a 20–30 % chance of at least one offspring, compared to an 80–90 % chance of motherhood in the general population (Morris et al. 2002). However, when thinking about the evolution and maintenance of a trait, one must not confuse current reproductive outcomes with the ancestral reproductive outcomes that prevailed for the vast majority of human existence. Measuring reproductive success in industrial cultures across the last several decades says almost nothing about the ancestral conditions in which the trait was designed by natural selection to replicate itself. For example, modern obese Americans have shorter life spans than the nonobese, but this does not cause scientists studying obesity to rule out adaptive theories for the development of genes that promote slow metabolism and the accumulation of body fat. Rather than recording current reproductive success as a benchmark of adaptiveness, considering how a trait may have been expressed and the outcomes of that expression in ancestral environments can be more illuminating.

One window into ancestral reproductive success is simply to look at patterns of sexual attractions that would have encouraged or discouraged mating in ancestral environments. Male sexual desire is usually considered category specific, strongly favoring either one sex or another (Chivers et al. 2005), such that there is a negative correlation between sexual attraction toward one sex and toward the other sex and men of all orientations with higher sex drives have more sex with a single preferred sex (Lippa 2007). This is not true of females, who show a weak positive correlation between attraction to one sex and the other (Lippa 2007). Looking across women of all orientations, the number of past sexual partners of one sex is positively correlated with the number of past sexual partners of the other sex (in contrast to a negative correlation in men; Kanazawa 2016). This may suggest that women who express same-sex attraction and

engage in more same-sex activities also report greater opposite-sex attraction and engage in more opposite-sex activities, potentially improving reproductive outcomes. However, this description may not apply to exclusively homosexual women, who show reduced attraction to males as a function of their attraction to females (Lippa 2007). In general, homosexual males express sexual attractions and behaviors that can be expected to have reduced reproductive success in ancestral environments, but it is less clear whether ancestral females would have suffered reduced reproductive success as a result of same-sex attractions.

Is Homosexuality an Ancestral Condition?

Comparative research has identified thousands of species that engage in homosexual acts, from house flies, beetles, and dragonflies; to shorebirds, geckos, and sunfish; to dogs, dolphins, and elephants. The particular practices, apparent purposes, frequencies, and phylogenies vary as widely as one could expect for a set of behaviors that span so many taxa. In almost every case, however, individual homosexual acts represent an infrequent, contextual, or strategic deviation from a typically heterosexual repertoire. The few exceptions to this include the domesticated male sheep (rams), of which only about 75 % show interest in mating with females, about 15 % show no mating interest whatsoever, and about 10 % are strictly interested in mounting other males. Among the apes, homosexual contact is frequent, particularly in our closest relatives, the chimpanzee and bonobo. Male-male cohorts dominate chimpanzee social structures and female-female cohorts dominate bonobo social structures; in both species, homosexual contact is used to maintain relationships, facilitate cooperation, and signal social dominance or submission (de Waal 1982). A recent phylogenetic analysis discovered that the frequency of same-sex genital interactions in primates is associated with social complexity and that male and female same-sex genital interactions may evolve independently (Fernandes et al. [in press](#)).

Deciding whether the character of human homosexual expression has changed substantially across the past several thousand years requires some speculation, but that humans have expressed some form of homosexual attraction and behavior since our common ancestor with the extant primates is nearly indisputable. Debate surrounds the translation and interpretation of texts and artworks that appear to describe homosexuality, but the debate centers on the exact nature of those sexual relationships, their exclusivity, and how they were perceived, not whether same-sex relationships occurred. It is an open question, for example, just how exclusively homosexual men and women may have been in ancestral hunter-gatherer societies. Across recorded history there have existed cultural entities that form in celebration of homosexual desire (e.g., the sixteenth century *mignons* of France, the seventeenth century *fanchonos* of Portugal, and the seventeenth through twentieth century *mollies* of England; Fone 2000). The term “homosexual” was coined at the emergence of the first large-scale homosexual cultural movement in the late nineteenth century in protest of German anti-sodomy statutes and has served to unite individuals under a broad conception of sexuality. When thinking about ancestral forms of homosexuality, cultural identities and sexual norms may not be applicable. For example, in ancestral communities on the scale of 20–80 individuals, perhaps no more than a couple of homosexuals of either sex would be present. These men and women would have been disconnected from an understanding of sexual variance and identity. Sexual norms likely included sexual fidelity and consent, but one can only speculate whether concepts of categorical sexual preferences or disgust toward same-sex activity were ancestrally significant.

As described, female sexual fluidity may suggest that the genes associated with homosexuality in females may not have suffered greatly reduced reproductive success in ancestral environments. A promising hypothesis for female homosexuality will be outlined ahead, but the high frequency of apparently exclusive homosexuality among males poses a greater challenge. The following two sections present evidence regarding whether human

male sexual orientations are fundamentally exclusive, i.e., psychological and behavioral data may help illustrate how male sexuality would have been expressed in ancestral environments.

Evidence Against Male Sexual Fluidity

Western men’s reported sexual orientation skews toward exclusivity, producing a bimodal distribution clustering on exclusive heterosexuality and exclusive homosexuality. This distribution is corroborated by implicit, physiological, and neural measures of sexual attraction in men. Self-reported sexual identity tends to match implicit associations of male and female stimuli as sexual targets in the implicit association task, with homosexual men showing rapid associations between sexual categories and male, more than female, stimuli (in contrast to heterosexually identified men; Snowden and Gray 2013). Several studies show that self-reported identity also aligns with penile arousal responses, with homosexual men showing larger responses to male stimuli than female stimuli and bisexual men showing no difference in response to male and female stimuli (Chivers et al. 2005). Regarding neural responses, the broad activity patterns of self-identified homosexuals exposed to male stimuli measured in an fMRI are similar to those of heterosexuals exposed to female stimuli, and differences in activity between preferred and non-preferred stimuli are similar in magnitude for heterosexuals and homosexuals (this study also found no evidence for conscious inhibition). Additionally, a taxometric analysis of sexual orientation in a sample of 14,118 American men demonstrates that homosexuality is a nonarbitrary sexual taxa defined by broad uniformity in sexual behaviors and attractions as well as mental health variables (Norris et al. 2015). Heterosexual and homosexual men report similarly stable sexual attractions across 6- and 10-year periods, whereas homosexual women and bisexual men and women show less stable sexual attractions (Savin-Williams et al. 2012).

Evidence in Support of Male Sexual Fluidity

Individuals of all orientations report overlapping and inconsistent sexual identities, behaviors,

and attractions, with anonymous and non-categorically framed studies showing higher reported identity-inconsistent sexual feelings. Just over half of exclusively heterosexual men and all homosexual men in a college sample reported questioning their sexual identity, indicating experiences ranging from hypothetical thoughts to sexual exploration (Morgan et al. 2010). Several studies have reported that just over half of self-identifying homosexual men report having had heterosexual sex at some time (e.g., 64 %, Whisman 1996). Whisman also found that 45 % of homosexually identified men report having had a romantically meaningful heterosexual relationship. In a longitudinal study of New Zealanders, among men who reported same-sex attraction at age 21, only half reported same-sex attraction at the final assessment at age 26 (Dickson et al. 2003). In a large retrospective study assessing lifetime sexual partners, 90 % of the 5.8 % of men who had at least one same-sex sexual partner since puberty also had at least one opposite-sex sexual partner during that time (Laumann et al. 1994). Although only 0.58 % of sexually active men studied by Laumann et al. reported exclusively homosexual sex since puberty, more than four times that percentage (2.4 %) reported exclusive attraction to the same sex, and 2.0 % reported a homosexual identity. These data suggest that behavioral bisexuality is common among men who identify as homosexual even if such behavior is transient or contextual.

Thus, homosexual and heterosexual identities are, for modern Western men, statistically and personally reliable and honest predictors of sexual attractions and behaviors. Yet the evolutionary and developmental sources of these patterns remain unclear, and when the boundaries of sexual identities are probed, inconsistency and diversity can be found. There is no consensus regarding how to interpret male sexual orientation; some researchers imply that ancestral male sexualities resembled modern categorical identities, and others argue that ancestral male sexuality was likely to be more fluid than modern identities suggest.

Is There an Evolutionary Puzzle?

Homosexuality in humans is heritable (Alanko et al. 2010; Mustanski et al. 2005) and currently responsible for reduced fecundity (Schwartz et al. 2010). In addition, human homosexuality is prevalent (Bagley and Tremblay 1998), and same-sex attractions and behaviors are ancient and likely to be deeply ancestral. These facts constitute an evolutionary puzzle, one that has generated fascinating evolutionary hypotheses and fruitful research avenues.

Proposed Solutions

There are several compelling theories for the maintenance of human homosexuality. Some of these theories describe homosexuality as the result of genetic abnormalities, developmental instability, social irregularity, or a pathogen. These hypotheses are interesting, if speculative, but the purpose of this discussion will be to review testable evolutionary hypotheses for human homosexuality. While male and female homosexuality both appear to have genetic components, the associated genes and etiology of homosexuality are believed to differ between the sexes. In particular, there exist reliable prenatal and childhood predictors of homosexuality in men, for example, greater numbers of older brothers and more female-typical interests are positively associated with homosexual identification (Bogaert 2006). Female homosexuality is more difficult to predict, has greater variability in its expression, and may evolve independently from male homosexuality (Alanko et al. 2010; Fernandes et al. *in press*). Differences of this kind may be attributable to differences in the selection pressures faced by ancestral males and females or differing modern cultural pressures (or both). Consequently, evolutionary theory may be applicable to both male and female homosexuality, but there is little reason to expect identical theoretical considerations. Thus, male and female hypotheses are presented separately. It could be argued that male homosexuality is more difficult to explain in an evolutionary framework. This is not only because females

show higher levels of sexual fluidity but also because male mating strategies benefit more than female sexual strategies from rapid, repeated, and diverse opposite-sex copulations. Thus, homosexual men who would refuse sex with women may be further removed from their maximally successful reproductive strategy than are homosexual women. Perhaps as a consequence, there exist more diverse hypotheses for the evolution of male homosexuality, although this may also be because there are more male researchers investigating these topics.

Male Hypotheses

The sexual antagonism hypothesis proposes that the genes that contribute to homosexuality in men facilitate reproductive success when expressed in women. In this view, the expression of male homosexuality is a costly by-product of selection for reproductive adaptations in women. This hypothesis was inspired by the finding that the female relatives of homosexual men show greater fecundity than the female relatives of heterosexual men, particularly in the maternal line (Iemmola and Camperio-Ciani 2009). Several studies have failed to replicate these findings (e.g., Schwartz et al. 2010), but the hypothesis remains tenable.

The overdominance or heterosis hypothesis describes the possibility that homosexuality is reported by men who carry homozygous recessive alleles that, when expressed in the more common heterozygotic form, confer selective advantages (e.g., such men are more cooperative, more lingual, and less aggressive; Zietsch et al. 2008). Here, androphilic men represent the tail of a distribution experiencing selection for a linked set of traits that produce female-typical behavior. In theory, only a small heterozygote advantage is necessary to produce a stable proportion of homozygotes, leading to the persistent, low rate of exclusive homosexuality. Sexual antagonism and overdominance are often supported via computer modeling techniques that allow researchers to set the parameters on a population and to simulate the gene frequencies that unfold over generations. Critics of these techniques argue that such models demonstrate only that the hypotheses are possible given the tidy parameters included in the

model, parameters which are not always empirically validated.

The genes that contribute to male homosexuality may survive via kin selection by supporting the reproductive success of kin who carry copies of those genes. If, by providing care to close relatives, a man enhances the overall reproductive success of his kin group, he may recoup the cost of his abstinence from reproductive sex. Evidence for elevated investment into kin among male homosexuals has been directly demonstrated on the island of Samoa among the fa'afafine (Vasey and VanderLaan 2010) but is not found in Western cultural environments (Rahman and Hull 2005). VanderLaan and colleagues point to elevated childhood separation anxiety in Western homosexual men as a sign that Western men are concerned for kin but may be culturally constrained from providing care. Kin-investing, transgendered forms of male homosexuality are also more frequent in cultures with more ancestral characteristics (smaller communities, simpler agriculture), which may suggest that ancestral male homosexual expressions were maintained via kin-directed investment in the context of transgendered homosexuality (VanderLaan et al. 2013).

The coalitional mating hypothesis emphasizes the comparative evidence for benefits gained by male chimpanzees from male-male alliances built upon sexual favors. The alliance or affiliation hypothesis thoroughly develops the human anthropological evidence for peripheral males gaining status through their sexual relationships with other men (Muscarella 2007). The homosocial hypothesis describes homosexual behavior as a natural extension of male-male and female-female cooperation serving to reduce violent mating rivalries. Underlying these hypotheses is the suggestion that direct, individual, and ultimately reproductive benefits can be gained via sexual behavior as a form of social influence. In other words, these hypotheses recommend that ancestral homosexual expressions were reproductively beneficial in certain social arrangements. Hypotheses of this kind have remained largely untested but are indirectly supported with reference to comparative and anthropological research. For

example, high-status male chimpanzees have been observed allowing low-status male grooming partners to mate with estrus females (de Waal 1982). Grooming between males frequently results in arousal and penile erection, and subordinate males can placate aggression by handling the genitals of dominant males. Similar patterns are observed among female bonobos. Anthropological research provides examples of lower-status human males gaining resources, status, and reproductive access via sexual relationships with higher-status males (Greenberg 1988). These relationships are typically intergenerational or transgendered in context, elevating younger or more feminine males in the mating market through sexual relationships with higher status men.

Female Hypotheses

Evolutionary theories for female homosexuality take a common form, closely resembling the affiliation hypotheses described for men just above. It is typically argued that female same-sex attractions aided ancestral females in creating and maintaining cooperative partnerships with other females. The function of these partnerships may have varied from interpersonal and sexual defense, to alloparenting and reciprocal child care, to status management and mate retention (Diamond 2009; Kanazawa 2016; Kuhle and Radtke 2013). Diamond points to the independence between arousability, or the capacity to become aroused, and proceptivity, or the motivation to initiate sex, in apes that lack conspicuous estrus (signs of fertility). If arousability is decoupled from proceptivity and continuous throughout the menstrual cycle, there is little evolutionary reason for it to discriminate between sexual stimuli of different sexes, i.e., becoming aroused by female stimuli will usually not inflict opportunity or energetic costs. Diamond argues that female sexual fluidity is thus a consequence of reduced pressure to curtail arousability in homo lineages (although she offers no direct adaptive benefits; Diamond 2009). Kuhle and Radtke (2013) highlight the benefits to child-rearing that can be gained by females who are willing to recruit female sexual partners. Bonobo females

provide the clearest nonhuman example of life-long female-female sexual coalitions, the members of which provide significant care to the unrelated offspring of their partners. Bonobo offspring receive basic care such as food sharing, defense, and transportation. These relationships involve sexual activities including genito-genital rubbing which frequently leads to orgasm. Human offspring are particularly altricial, requiring a lengthy and costly period of development before becoming self-sufficient. Without some form of outside care, researchers have argued that ancestral human mothers would have found it extremely difficult to raise offspring, particularly in cases where the father was not present. In modern hunter-gatherer societies, alloparental care from unrelated females (usually other mothers) is common and is associated with improved offspring survival. Sexual activity and especially orgasm promotes associations between the sexual partner, positive sensations, and social-bonding hormones including oxytocin. It is hypothesized that ancestral females took advantage of this capacity to manufacture social commitment in order to facilitate reciprocated child care. Recently, Kanazawa (2016) underscored the conflict resolution functions of same-sex interactions, proposing that in ancestral polygynous arrangements, females who found reliable ways to diffuse conflict would have been better able to collaborate for their own benefit. In other words, women who lacked a capacity for sexual fluidity may have suffered from an inability to function in recurrent polygynous mating situations. Each of these theoretical perspectives seeks to explain female sexual fluidity without necessarily addressing the appearance of exclusive female homosexuality. Exclusive female homosexuality is uncommon, often transient, and appears to be linked to higher than average prenatal exposure to androgens (Savin-Williams et al. 2012). This leads many researchers to consider it inappropriate or unlikely to fit a directly adaptive theory to the phenomenon. Again, one can only speculate as to the influence that social environments and identities may have upon modern sexual orientations, but such effects may be worth considering.

Conclusion

Human homosexuality has puzzled evolutionary thinkers for decades, its existence challenges basic principles of natural selection, and this problem has inspired creative thinking on the topics of ancestral mating patterns, comparative sexuality, reciprocal and kin altruism, and genetic inheritance. Many advances in our understanding of sexuality and mating in general are owed to the study of homosexuality, and it is a research avenue that continually reveals new questions and invites original answers. The study of homosexuality also has unique implications in the social and political world, as homosexuals around the world suffer immeasurably for harboring desires deemed taboo. One hopes that a growing understanding of homosexuality, particularly its evolutionary and developmental origins, will help to illustrate how deeply ancestral, universal, and ultimately healthy same-sex attractions and behaviors are. Progress on this topic is encouraging and indicates that public perception can be effected by conversations in science and that the public are interested in learning more about human sexual variance.

Honor Code

[Honor concern](#); [Moral values](#); [Social identity](#)

Definition

Honor is defined as a person's worth in his/her own and others' eyes (Rodriguez Mosquera et al. 2010). This set of socially accepted norms further

highlights the significance of a person's reputation and social image (Rodriguez Mosquera et al. 2008).

Social and Cultural Underpinnings of Honor Code

According to Pitt-Rivers (2001), honor, simultaneously, is a person's self-reflection and representation of their moral values in the social setting. Consequently, honor is a cohesive measure for determining social identity, which exists in one's interpersonal relationships established in the society. They further added that honor code applicable in a culture regulates individuals by guiding their moral evaluation and judgment of others, influencing people's actions before society, and measuring of social status (Pitt-Rivers 2003). Blincoe and Harris (2011) suggested that we use other people's perception of our social image to draw our own social image in their eyes. Other people's behavior toward us translating respect or disrespect for us is an important indicator in this regard. Such opinions may be a result of our own behavior, or may be behavior/s exhibited by the members of our closest social groups like our family. Moreover, these perceptions may be based on gender roles prevalent in a culture.

Cultures with highly traditional attitudes toward sex-roles associate gender-specific honor trepidations (Rodriguez Mosquera 2011). Moreover, *family honor* refers to a concept, which requires a person to behave in a certain manner, which defends the honor of the entire family as well as improves the reputation-damaging behavior of other family members. A person's reputation significantly revolves around protecting and respecting their family name (Rodriguez Mosquera et al. 2010). Literature associates different factors like importance of family's reputation, the existence of family secrets, and satisfaction of a family with this aspect of respect (Vangelisti 1994) in addition to their tendency not to report sexual attacks (Lewis 2003).

Integrity, on the other hand, is the status of a particular person given to them because of their

fairness in dealings and honesty. This states the image of a person to the social group as loyal and trustworthy (Rodriguez Mosquera et al. 2010). Whereas a person's reputation being assertive as a male gender role, supporting their family, working hard, having sexual capability, and defending themselves against invectives are the measures of their *masculine honor* (Nisbett and Cohen 1996). Many violent crimes and behaviors have been strongly associated to male honor (Guerra et al. 2013), as well as being directly related to other concepts like fearlessness, superiority, respect, and bravery (Neff 2001). On the contrary, *feminine honor* is deemed as the responsibility of a woman to submit to the gender role ascribed to her by her culture and to uphold the reputation by behaving with chastity and sexual restraint. Because it is considered that a disgraceful behavior can bring shame men's associated and bring down the family name also. For that reason, proper conduct is significant to defend the family's name (Rodriguez Mosquera et al. 2010).

Conclusion

Generally, our behavioral expressions are related to our sense of inclusion in a social group, as well as the status ascribed to us by the group. A person's self-worth and their social image are strongly interconnected in cultures, which adhere to honor codes. Traditional cultures, in particular, strongly emphasize on honor because elements like family values, harmony, and respect are emphasized in such cultures (Markus and Kitayama 2003).

Definition

A culture that involves and supports hooking up or uncommitted, short-term sexual acts between two people who are not involved in a long-term relationship with each other.

Introduction

One of the most primal human desires is the want to engage in sexual behaviors. Traditionally, the most important goal of sexual intercourse was mating for reproduction and the continuation of genes, which has favored long-term relationships. However, reproduction is not the only goal for people to have sex. There are also other goals like physical gratification and fulfillment of emotional needs (Birnbaum and Gillath 2006). Over the past 60 years, many societies have become more sexually liberated, and the use of birth control (e.g., condoms, oral contraceptives) has increased (Garcia et al. 2012). With these changes, the sexual goals of physical gratification and emotion fulfillment have increased their prominence. Unlike reproductive goals, which tend to favor long-term relationships, these goals may be fulfilled with long-term or short-term relationships. Currently, hookups are one of the most common ways of achieving these goals in short time and have been told to become a culture. A “hookup” occurs when two people who are not involved in a long-term relationship with each other engage in a brief sexual encounter, which may involve kissing, sexual touching above or below the waist, oral sex, or sexual intercourse.

Creation of the Hookup Culture

The roots of the hookup culture go back to the 1920s where societal norms started to change, mobility increased, and medicine and science had advanced developments. For example, with the advent use of cars, people’s mobility increased, which led to a decrease in the time spent with parental supervision, which led young men and women to have more freedom (Stinson 2010). The 1920s was just the beginning of many changes, and the number of women who wanted to follow the role of wife and mother reduced after the advances in the contraceptive technology in 1960 (Heer and Grossbard-Shechtman 1981). Again in the 1960s with the sexual revolution, young adults became more sexually liberated,

making them more open to short-term mating practices (Garcia et al. 2012). This movement toward sexual liberalism continued with the rise of feminism and increased numbers of females in the workforce and university students. Long-term relationships were viewed as potentially interfering with career goals, so young adults started to substitute quick hookups for long-term relationships that usually require longer investments (Heldman and Wade 2010). As a result, the age of first marriage increased, creating time for young adults to be sexually active but not ready to settle down (Garcia et al. 2012).

Although it seems as if culture and sexual lifestyle has changed in the new millennia, data from the Generals Social Survey (GSS) indicates otherwise. Since 1972, the GSS has been conducted by the National Opinion Research Center to assess the experiences, attitudes, and practices of United States residents. GSS data indicate that there is only a modest difference between the waves from 1988 to 1996 and 2004 to 2012 in sexual behavior. Young adult (18–25) respondents from the 2004 to 2012 waves did not report more frequent sex or more sexual partners than young adults in the 1988–1996 waves. However, respondents from the 2004 to 2012 waves were less likely to report sex with a regular partner, and more likely to report sex with a casual dating partner or friend (Monto and Carey 2014). This small change between the two groups suggests an increase in the hookup culture and is consistent with changes in “sexual scripts.” *Sexual script theory* argues that sexual behaviors are initiated with a set of these “scripts” that people use to shape and understand sexual encounters (Simon and Gagnon 1986). Scripts are a representation of the conceptualization of social behavior, and they direct behaviors for what should be done and who should do it in a context. So if people are living in a hookup culture today, it appears to be similar to the culture of the previous generation just with a different name (Monto and Carey 2014).

The origins of these scripts are not defined thoroughly, but evidence indicates that popular media influences the design of these scripts; and media is also an important factor in the growth of this culture (Garcia et al. 2012). As time passes,

people are exposed to more mass media than ever before, and TV programs use sexual images, themes, and references more than in previous generations (Aubrey 2004). In the same vein, a content analysis shows that more than 90% of the songs in Billboard's Top Ten lists include sexual messages in their lyrics (Hobbs and Gallup 2011). A similar trend in the use of sexual themes can also be seen in print media in the depiction of smartphone apps designed for matchmaking. Currently, matchmaking applications are one of the most used mediums for people to meet new potential mates, "Tinder" being the app with the most users. Although studies show that people's motivation to use this application is more for "love" than "casual sex," the application is presented as the "hookup app" (Sevi et al. 2017). This increase in sexual exposure has been argued to be a possible reason for the endorsement and participation in the hookup culture, just as the relation between aggression and media violence (Heldman and Wade 2010).

Conclusion

The emergence of the "hookup culture" can be traced back to the early twentieth century. Throughout the decades, advances in science and technology and changes in societal norms have contributed to shifts in the goals of sexual behavior and the structure of interpersonal relationships. Hookups include a broad range of sexual behavior from kissing to sexual intercourse and may consist of a single encounter or multiple encounters. This culture has started to emerge with sexual liberation and has been going on since. However, it has not had a name. With the help of media and the evolution of sexual scripts, this culture of brief and uncommitted sexual acts has found its name as the "hookup culture."

Definition

Sexual orientation is defined as “an enduring pattern of emotional, romantic, and/or sexual attractions to men, women, or both sexes” (APA 2008).

Introduction

Sexual preferences are focused to be expressed during the whole process of courtship and mating. Thus, depending toward which gender those behaviors are aimed to, a person may be defined as heterosexual, homosexual, or bisexual. In this sense, sexual orientation has a motivational (desire) component and also a behavioral component (courtship behavior). In homosexual persons both components (motivational and behavioral) are orientated toward their same sex group. These feelings are expressed during all the life span, while the behavior might be expressed or not. Psychological research (questionnaires, tests)

through many years and in different historical periods has demonstrated that sexual orientation ranges along a continuum, from exclusive attraction to the opposite gender to exclusive attraction to one's own gender (Kinsey et al. 1948; see the Kinsey Scale in this volume), suggesting different motivational and behavioral brain networks for sexual orientation. Only 3–10 % of the population are exclusively attracted to individuals of their own sex, but this minor number cannot be reason for exclusion, discrimination or a phobic social attitude toward them, because there are none objective links nor serious correlation data at all that might proved any relation between homosexual orientation to antisocial or social disruptive behaviors.

Perhaps Sigmund Freud was pointing a second type of mainly late-onset homosexuality in human when he stated parental styles and childhood experiences might have an effect on adult sexual orientation. However, psychoanalysis was not so correct when assured male homosexuality might be due to an authoritarian father and a wrong erotic relation toward the mother (Puts et al. 2006). Other wrong interpretations as sexual orientation like a choice might have been derived from this late-onset explanation: it has been wrongly considered as a bad habit that could be changed, and many people have unfairly suffered for this confusion. Besides psychoanalysis, many other methods have been used in the attempt to bring about changes in sexual orientation: castration, administration of testosterone or estrogens, apomorphine, psychosurgery, electroshock, etc., but none of these interventions have led into a well-documented change in sexual orientation (see Savic et al. 2010). In the 1960s and 1970s, in the context of the behaviorism and its *tabula rasa* concept about unlimited brain plasticity for sexual identity, some clinical practices have had quite devastating effects, such as in the John-Joan-John case (for revision, see Garcia-Falgueras and Swaab 2010).

Genetic information coming from a father (man) (XY) and from a mother (woman) (XX) are inherently part of all of us. However, sexual preferences for having a life partner, for creating a family with another adult in a human being commitment and taking care of an

offspring, are a complex set of feelings that might be defining the whole complexity of sexual orientation as a path for life.

Main Text: Orientation and Organizational Changes

It is important to notice female and male homosexuality are not equivalent nor similar but depend at least partly on different interactions with hormones during fetal development which creates, organizing for later activation, specific brain networks for each gender. It has been proved the production of testosterone and its conversion into dihydrotestosterone between weeks 6 and 12 of pregnancy are essential for the completion of a boy's reproductive system, while in the girl's reproductive system, it might be essential not having such high amounts of plasma androgens during the same period (Garcia-Falgueras and Swaab 2010). In men, testosterone levels and the efficiency of its receptor during the process of their body development in the womb are relevant for sexual orientation and gender identity. In women higher testosterone levels may also have an effect on adult game preferences and spontaneous drawing, for congenital adrenal hyperplasia cases (CAH). On the other hand, homosexual women have been shown to have higher free cortisol stress concentration compared to heterosexual women, while homosexual men have lower overall cortisol concentration compared to heterosexual men (for review, see Garcia-Falgueras and Swaab 2010). Due to these differences in early organizational hormonal effects during embryonic development, adult activation might also be different for homosexual orientated people: for instance, homosexual men are more sensitive (react more intensely) after oxytocin administration when facial stimuli are presented compared to heterosexual men (Thienel et al. 2014).

In the brain *in vivo* studies have proved that the hypothalamus, in homosexual man and woman, has a different activated areas to specific smells related to reproduction than the hypothalamus in heterosexual subjects (Savic et al. 2010). These results have been replicated with other methods

and different subjects: it was found gray and white matter are differently concentrated in certain brain areas for man and woman homosexual and heterosexuals, such as those related to olfaction as the perirhinal cortex. In the resting state, the amygdala is asymmetrically connected in homosexuals (men and women) (Savic et al. 2010; Garcia-Falgueras and Swaab 2010). Left-handed people are slightly more likely to be homosexual than right-handed people (Puts et al. 2006). Such a balance between our inner masculinity and femininity, as well as that equilibrium between symmetry for both sides of the body, seems to be organized early in the womb. For further details, see chapter entitled ► [“Relationship Between Sexuality and Gender”](#) in this volume.

Reviewing current scientific literature on the topic, there are several effects during gestational critical period (i.e., organizational changes because of hormonal modifications in plasma levels or in hormone receptor efficiency) that might cause or have a consequence together with sexual orientation. Their presence in the womb might lead to an organized specific grown-up characteristic. Some examples about the possible effects of changes in hormonal levels during gestation on adult behaviors, phenotypes or morphologies have been proved to occur in (a) female humans with adult polycystic ovaries, (b) specific length of fingers and length proportion between them in adulthood, (c) brain laterality for right or left handed, (d) large percentage of bi-/homosexuality in female offspring during the 1950s because of early exogenous diethylstilbestrol (DES) treatment for pregnant mothers, and (e) large percentage of bi-/homosexuality in females because of specific steroid mutations such as congenital adrenal hyperplasia (CAH), androgen insensitivity syndrome (AIS), etc. (for rev. see Savic et al. 2010; Garcia-Falgueras and Swaab 2010), and hormones that might affect the mother's immune system and having an effect toward her male offspring's sexual orientation, depending on the order of birth for boys and the amount of previous brothers (Puts et al. 2006). Experimental procedures pursuing a causal relationship between these variables are simply not possible to implement because of ethical principles, but correlations do strongly exist.

In some few cases, sexual orientation has been expressed later in life, as it has been described for gender dysphoria patients, in a late onset (Auer et al. 2014). This is happening in some particular cases in humans, for instance, while they are in prison, but there are no good experimental evidences to describe it as an adult change in sexual orientation. Cases in humans about plastic adult learnings have been described but they might be related most likely to another brain region such as the hippocampus, as it has been reported to occur in taxi drivers and musician (Hahn et al. 2016). The existence of a biological substrate of sexual orientation is unquestionable, because human existence is rooted in our biology, but the neural basis of motivational versus behavioral sexual orientation is not completely established yet, for heterosexuality nor homosexuality (Gooren 2011).

In animal kingdom curious cases in beetles have been described. In some species of insects, in which the recognition cues of females and males overlap to a certain degree such as beetles, homosexual behavior is a consequence of an adaptive discrimination strategy with a functional meaning of avoiding the costs of making rejection errors. This studies might be suggesting that sexual orientation in certain species is a result of a balanced calculation between low/high costs of a rejecting female versus low/high costs of an accepting male (Engel et al. 2015). Although currently there are no experimental evidences about this hypothesis in humans.

However, animals and not human beings have another set of determinant variables strongly linked to reproductive goals and defining their intercourse behaviors. Patterns of behavior in vertebrate species, such as those related to territorialism or aggressiveness, vary and change as stages during the reproductive seasons in the life cycle progress while it is activated by specific hormone signals (Wingfield et al. 1997). Concerning to animal research, there are plenty examples of homosexual behavior: in rodents and rams, those behaviors have been related to the hypothalamus neuromorphology, i.e., in rams, ovine sexually dimorphic nucleus, (oSDN) and in rats, medial preoptic nucleus (MPON). Some parallelisms in humans, i.e., suprachiasmatic nucleus (SCN) and

interstitial nucleus of the hypothalamus-3 (IHAN3), were found as well in extension to human homosexual behavior (Swaab and Hofman 1990; Levay 1991; Garcia-Falgueras and Swaab 2010). As far as our knowledge, no histological tissue studies have been done to localize the motivational aspects of sexual orientation. More relevant information is available for the reader in the chapter of this volume entitled ► [“Biology of Human Gender, The”](#).

Many times in history, love potion antidote has been tried to supply for heterosexual love in some cultures. Further details can be read in the chapter of this volume ► [“Mate Retention and Romantic Attachment”](#). Love has been considered as a serious illness. Indeed George Bernard Shaw defined love as one of the “most violent, most insane, most delusive and most transient of passions” (for revision, see Earp et al. 2013). Those data are pointing out that extreme passions, any sort, might be a considerable dangerous factor against life survival and contradictory in evolution terms. Much research suggests that while sexual orientation might be malleable at certain stages of the life span, it is fixed by the time we reach adulthood and is beyond further influence (Savic et al. 2010).

Conclusion

Sexual orientation is defined as “an enduring pattern of emotional, romantic, and/or sexual attractions to men, women, or both sexes.” In this sense, sexual orientation has a motivational (desire) compound and also a behavioral compound (courtship behavior). The production of testosterone and its conversion into dihydrotestosterone between weeks 6 and 12 of pregnancy are essential for the completion of a boy’s reproductive system, while in the girl’s reproductive system, it might be essential not having such high amounts of plasma androgens. Changes in this proportions might caused adult behavioral and motivational modifications. Some cases of late onset for sexual orientation have been described, i.e., prison, although there are no experimental evidences. Specific brain areas in mammals have been found to have a connection with sexual orientation behavior (i.e., ovine oSDN, in rats MPON,

humans SCN, and IHAN3). Those data are pointing out the fact that sexual orientation might be fixed by the time we reach adulthood and is scarcely beyond further influence.

Hormone Effects on Human Fetal Development

Catherine DeSoto
Psychology, University of Northern Iowa,

Prenatal Programming, Cortisol

The evidence that phenotype is set partially based on prenatal hormonal exposure is overall strong.

Such effects make sense within the evolutionary psychology framework.

Hormone levels that a developing fetus experiences can result in long-lasting phenotypic differences in the individual. Because the maternal blood supply is the route by which a fetus will be exposed, mother's levels – and her experiences – can affect development.

High levels of stress during pregnancy result in higher levels of the hormone cortisol as does exogenous ingestion of certain medicines (e.g., steroids) or certain foods (i.e., licorice). In any case, there is evidence that exposure of the fetus during prenatal development will alter early programming, causing differences in metabolism and other physiological parameters. The effects are long term or permanent. Combined with experimental methods employing animal models (see Weinstock 2008), there is converging evidence implicating a causal pathway for human development. The human placenta features 11 β -hydroxysteroid type 2 (HSD2) that works as a barrier to prevent excess cortisol exposure for a fetus; the enzyme converts the active form into an inactive form when it crosses the placental barrier. Animal research suggests that this enzyme can be more or less active due to starvation, various kinds of inflammation, or general stress, thus altering fetal exposure to glucocorticoids. Broadly, high levels of glucocorticoids in the mother result in lower birth weight and increase in HPA activity and changes in the overall metabolic profile. For example, increased cortisol, higher susceptibility to diabetes, and cardiovascular risk have all been well documented (see Reynolds 2010; Reynolds 2013). The general patterns suggest that *more* cortisol encountered prenatally results in generally *more cortisol* when there is not an acute stressor present and a *blunted increase during times of acute stress* (O'Connor et al. 2013). Also of considerable interest are the effects on the developing brain. McEwen in 1999 demonstrated a definite susceptibility of the developing brain to glucocorticoids. Since that time, several key findings have emerged. Buss et al. (2012) have found evidence for an early window of

sensitivity to cortisol in girls. Specifically, early exposure to high cortisol during gestation was associated with significantly increased size of the amygdala in seven-year-old girls. The amygdala is associated with linking and responding to fear or anxiety-producing external stimuli. Research has documented that levels of cortisol (measured in utero) predict later impairments in measured cognitive development (Bergman et al. 2010).

Evolutionary psychologists generally conceptualize an individual as a combination of genotype framing allowing for a range of final outcomes that are fine-tuned based on expected or encountered environmental circumstances. As a whole, it appears that prenatally experienced increased cortisol leads to alterations of the offspring's HPA, thus causing myriad changes, including low birth weight and altered glucose processing (e.g., later susceptibility to type 2 diabetes) and altered response to experienced stressors throughout life. From an evolutionary psychology perspective, it is interesting to observe that deleterious effects may be most pronounced when a mismatch between utero environment programming and experienced adult environment is likely greatest. For example, low birth weight in tandem with adulthood obesity was a stronger risk factor than either variable alone (Li et al. 2010). This suggests the possibility that the function of prenatal programming may be to somehow prepare for adult environment most likely to be encountered.

Conclusion

Certainly, the environment encountered determines which behaviors and phenotypes are the most adaptive. Hormones may serve as a signal to alter the developing fetus toward a phenotype more adaptive to expected circumstances. Alteration of the physiology and behavior of offspring via the levels of maternal corticoids could be plausible vehicle for such fine-tuning to occur. In any event, evidence that hormonally based prenatal programming alters the phenotypic outcome of the individual, especially glucocorticoids, is strong.

Hostile Masculinity

Tiffany D. Russell

Department of Psychiatry, Harvard Medical School/McLean Hospital, Harvard University, Belmont, MA, USA

Definition

A latent personality construct comprised of aggressive, defensive, and narcissistic traits and a tendency to derive sexual gratification from dominating and controlling women. Hostile masculinity predicts sexual and nonsexual violence against women, and it is one of the two proximal trait constellations directly predicting male sexual violence against women in Malamuth et al.'s (1991) Confluence Mediation Model of Sexual Aggression.

Introduction

The Confluence Mediation Model of Sexual Aggression (CMM or Confluence Model) is a multifactorial, evolutionary-based model of sexual violence perpetration first proposed by Malamuth (1986). This groundbreaking model has proven robust in cross-sectional, longitudinal, and laboratory studies, and it has been replicated in a variety of populations, including incarcerated, university, and community samples of men (for a review, see Malamuth and Hald 2016). The central premise of the CMM is that two major constellations, hostile masculinity and sexual promiscuity/impersonal sex, are synergistic (interactive) and predict sexual violence perpetration better than an exclusively additive model of the individual risk factors. In the absence of the sexual promiscuity constellation, hostile masculinity predicts nonsexual violence against women (Malamuth et al. 1991).

Factors Contributing to Hostile Masculinity

Hostile masculinity is conceptualized as an antagonistic, insecure, grandiose personality profile exemplified by manipulative, callous, distrustful, and hostile attitudes against women (e.g., Malamuth and Hald 2016). Although seemingly similar to constructs like hypermasculinity, men with high levels of hostile masculinity direct their aggression toward women specifically, whereas hypermasculine men are less discriminating when selecting their targets of aggression (Malamuth et al. 1996). Childhood maltreatment (e.g., abuse, neglect, domestic violence) appears related to the development of psychopathic/narcissistic traits and hostile masculinity. There are several hypotheses for the development of the malevolent personality styles that lead to hostile masculinity. These involve men modeling the violence against women that they witnessed in childhood, as well as engaging in antisocial activities at an early age (e.g., Malamuth and Hald 2016; Malamuth et al. 1991, 1996). Additionally, neglectful maternal relationships lead to anxious maternal attachments and cognitive distortions, which contribute to the perception that women are unreliable and unworthy of respect (Russell and King 2016). These early life experiences, along with living in subcultures encouraging the expression of stereotypically masculine traits (e.g., dominance, competitiveness) and punishing the expression of stereotypically feminine traits (e.g., kindness, empathy), foster attitudes supporting violence against women and hostile masculinity (e.g., Malamuth and Hald 2016; Malamuth et al. 1991, 1996).

From a statistical perspective, the CMM is a structural equation model, and hostile masculinity is an endogenous latent variable with a direct path to sexual violence perpetration. Hostile masculinity serves as a mediator between broad, general personality types (e.g., psychopathy, narcissism) and sexual aggression. Observed variables loading on hostile masculinity include scales assessing hostility toward women, sexual dominance, and rape myth acceptance.

Exogenous personality predictors of hostile masculinity relate to narcissism, psychopathy, and sadism. Hostile masculinity also mediates the relationship between childhood maltreatment and sexual violence (e.g., Malamuth et al. 1991; Russell and King 2016). In an answer to Malamuth and Hald's (2016) call for research to "elucidate more precisely the mechanisms that link 'higher order' general hostile/antisocial factors...to the 'narrower,' more proximate factors predictive of sexual aggression" (p. 66), Russell and King (2017) found hostile masculinity mediated specific facets of psychopathy and narcissism. These lower order facets included grandiosity, cognitive/perceptual dysregulation, traditional/conventional beliefs, and interpersonal suspiciousness.

Evolutionary Theory and Hostile Masculinity

Comparing and contrasting the evidence for sexual violence being an adaptation or a by-product of an adaptation is beyond the scope of the current entry (for a discussion of this topic, see ► "Aggression for Sexual Access"). However, Malamuth et al. (2005) make a convincing case for sexual arousal to force being a specialized psychological adaptation motivating sexual violence that can be briefly summarized. Malamuth et al.'s (2005) contention is that, in order to be an adaptation, sexual violence must have contributed to some men's fitness increases some of the time, and it had to occur often enough to overcome fitness costs (e.g., injury, death). If that occurred, and assuming all humans evolved with common psychological mechanisms, then a sexual violence mechanism could have evolved. Implicit in these assumptions is that all men have the potential to become sexually violent when individual experiences (e.g., childhood maltreatment, anxious maternal attachment) "activate" the evolved psychological mechanism. The factors loading on hostile masculinity (sexual dominance motives, hostility toward women) seem to be a manifestation of

this evolutionary specialization. Thus, men with sufficient levels of the sexual violence mechanism exhibit a relatively persistent hostile masculinity *trait*, as opposed to transient *states* of hostile masculinity.

There is empirical support for the sexual violence adaptation hypothesis. Beyond the considerable evidence for the CMM and hostile masculinity, laboratory research has demonstrated men can be primed for sexual arousal to force by simulating female rejection of sexual advances. For example, college men who were insulted by a woman became more sexually aroused by non-consensual sex descriptions than consensual sex descriptions (Yates et al. 1984). Baumeister et al.'s (2002) development of a narcissistic reactance theory for rape and coercion also described numerous studies involving narcissistic men becoming sexually violent when rejected by women. Indeed, there seems to be support for an evolutionary adaptation related to sexual arousal to force in the sexual violence literature, although it is premature to discount the possibility of a by-product at this time.

Conclusion

The present summary described factors contributing to hostile masculinity, as well as evolutionary concepts associated with this cluster of personality traits. Hostile masculinity is a latent construct in the Confluence Mediation Model of Sexual Aggression. It directly predicts sexual violence perpetration in men who have co-occurring traits associated with the sexual promiscuity/impersonal sex constellation, and it predicts nonsexual violence against women when sexual promiscuity is absent. Hostile masculinity manifests as hostility toward women and sexual dominance motives, and it mediates the relationship between broad personality traits (e.g., narcissism, psychopathy) and sexual violence perpetration. Hostile masculinity may be the manifestation of sexual arousal to force, a potential evolutionary adaptation for sexual violence, although additional research in this area is required.

Definition

The understanding of foundations of psychology in respect to biology and of evolutionary psychology's ability to coalesce various academic domains that advances the modern science of psychology.

Introduction

The battle between *nature* and *nurture* continues to be incessant within the social science communities. Evolutionary psychology, however, is a field that takes initiative to become an exemplar of academic consilience. The inception of psychology and biology itself segregates themselves from the other, which distorts the perspective that behavior can be adaptations like physicality. Humans are organisms that possess brains that abide to the laws of evolutionary biology. Societies similar to modern Western ones exploit the operations of psychology as well as the ancestral conditions in which psychology evolved. When the comparisons between ancient and modern environments are established, evolutionary psychology will become a pertinence to the modern study of mind and behavior.

Psychological Attributes as Biological Adaptations

Like organisms, academic disciplines evolve. Psychology is widely accepted as a descendent of biology; however, parsing one from the other has resulted in academic complications and controversies. Behavior as an adaptation, sometimes called an *instinct*, serves as an intersection of psychology and biology. Behavior of all sorts rests on the foundations of the nervous system or the brain, which has and always will be subject to the principles of biological evolution.

Because the rates of both biological and cultural evolutions are far from identical, adaptations from exponential generations ago endure the journey to the contemporary generations. Like a biological adaptation, a psychological adaptation is a feature that ultimately enhances its genes reproductive fitness as a result of gradual modification generation to generation. Any adaptation or any seemingly designed characteristic is not *always* of service to the organism that possesses it. *Mismatch theory* posits that evolved features that were adaptive in certain environments are maladaptive in others (Buss 2015; Barkow et al. 1995).

Modern society and enduring cultures, intuitively, are distinct from one another; however, many, if not most, of them share similar qualities. Language, religion, sexual preferences, division of labor, and hierarchal structures, for example, are never identical culture to culture but certainly are in respect to their service to those who practice them. As a perspective of psychology, evolutionary psychology unites a variety of academic domains, which poses original questions on behavior. The lens of evolutionary psychology is capable of enlightening the current conundrums traditional psychologists frequently confront. As a truly integrative discipline, evolutionary psychology could contribute to the sciences of most, if not all, of the branches of psychology.

Psychology as a Descendent of Biology

The foundations of psychology lie within the nervous system. The central nervous system of modern humans or *Homo sapiens* is the brain, the hub of cognition and behavior. Like any organ, the brain is a product of gradual modification on the basis of evolution via natural selection. The accumulation of selective forces and environmental pressures that humans encountered throughout their evolutionary history ultimately forged, like any other biological entity, the brain (Palanza and Parmigiani 2016).

Distinction between the mind and body has been under debate since their inception. Science, today, advocates the dualistic view of the mind and body by delegating their studies into two different disciplines: psychology, which imperialized the study of mind and behavior, and biology, which imperialized the study of the body and its operations. This dualistic view yields unexplained discrepancies between neurological psychologists and molecular biologists. While every brain and mind is popularly believed to be different between every individual, merely every bodily aspect is inherited, including neurochemistry (Pervin 2009).

The terms *psychology* and *biology* themselves are a mean to their academic segregation. The underlying causes of mental illnesses and bodily diseases are almost indistinguishable from each other. The notion that psychological and

biological principles are related is frequently condoned from both disciplines, yet one cannot survive without the other. As a descendent of psychology and biology, evolutionary psychology is the first scientific discipline that applies established biological principles to the study of human mind and behavior.

Life history theory predicts the pace of a species' maturation when given its ancestral history and modern environments. Furthermore, life history theory can be used to predict characteristics such as lifespan and degree of social cohesion. Mental traits that foster socialization develop non-randomly from species to species. Even major brain regions like the amygdala, hippocampus, and frontal lobes begin and finish developing during specific times of an organism's lifespan (Figueredo et al. 2006).

Somatic effort, an organism's pursuit for self-growth and maintenance, transforms into *reproductive effort* or the will to obtain the means to procreate. Reproductive effort may then evolve into *mating effort* to select a particular mate from a selection of potential mates, which may transform into *parenting effort*, which is an organism's nature to bear and rear its offspring they can sustain themselves. The relationship from somatic to parenting efforts enables life history theory to predict the number of offspring typically reproduced, sex differences in mating strategies, years of adolescence, risk-taking tendencies, and even social deviance (Figueredo et al. 2006).

Sexual selection theory also has implications on the nature of parenting. Sexual selection is the preference of one sex to choose to mate with members of the opposite sex. Generations of sexual selection result in more unique characteristics that distinguish one sex from the other. Sexual selection influences almost all of the nuances of a species' reproductive nature. Relative to males, females more often invest both more and a variety of efforts to the overall fitness of their young, especially within the mammalian kingdom. Evolutionary psychology endorses the relationship between sexual selection and *parental investment theory* as it provides new insights to explain human parenting and mating behavior (Buss 2015; Geher 2014).

Behavior or acts of expression may be viewed as a physical adaptation enhancer. Scientists within the domain of ethology effortlessly explain animal behavior from an evolutionary standpoint, yet the nature of biology is condoned when examining behavior of *Homo sapiens*. Physical structures that characterize an organism are designed by biological evolution (Cosmides and Tooby 1997; Palanza and Parmigiani 2016); the architecture of the brain changes in order to guide its host to survive without excessive discomfort.

Mental traits, like their physical counterparts, are adaptations. Behavior is a result of *both* genes and environments (Cosmides and Tooby 1997). From an ultimate perspective, the origins of behavior can be traced to the principles of biology. This perspective does not assert that every action or single behavior is of a survival or reproductive service; rather it posits that psychological phenomena are not completely dependent on experience and are partially inherited qualities from previous generations.

Evolutionary Mismatch Theory

Traditional social sciences have an extensive history of putting nurture before nature. This standard social science model (SSSM) originates from the false conception that mind and behavior is a product of only experience, which is also called the *blank slate* (Barkow et al. 1995; Figueredo et al. 2006). Given that numerous regions of the brain are functionally specific (Cosmides and Tooby 1997; Palanza and Parmigiani 2016), an adaptationist approach to psychology may be scientifically advantageous (Buss 2015; Barkow et al. 1995; Geher 2014). The SSSM significantly lacks this perspective, which transcends to a plethora of unasked questions.

It is necessary to reiterate that the rate of cultural evolution is far beyond the rate of biological evolution, for biologically complex organisms. The human brain's evolution predominantly derives from when early humans were hunter-gatherers (Cosmides and Tooby 1997). The persistent problems human ancestors faced – droughts, famine, competitions for resources, predators, and disease, to name a few – serve as ultimate and unique selective pressures.

Individuals with cognitive advantages over the others better adapt to evolutionary pressures over time. The more consistent the evolutionary pressures, the more time the mind has to specialize in each evolutionary hurdle (Buss 2015; Barkow et al. 1995; Geher 2014).

The position that human psychology is chronologically displaced due to the rapid rate of change of culture and society leads evolutionary psychologists to espouse *evolutionary mismatch theory*. A psychological trait is either an adaptation, a by-product of other adaptations, or a random effect (Buss 2015). A central theme of evolutionary mismatch theory is that an adaptation is not always adaptive or maladaptive (Caporael 2001). Evolutionary psychological theories and hypotheses frequently result from this popular theory, many of which assist the field to explain contemporary psychological phenomena.

A lucid example of mismatch is the penchant for sugary and fatty foods. Hunter-gatherers would not be called *hunter-gatherers* if there were a McDonalds or a supermarket in their environments. The conditions hunter-gatherers evolved from had a dearth of food and nutrition. Humans who yearn and seek for fatty foods have advantage over those without it or those with a lesser degree of it. Today in developed nations, fast-food restaurants and supermarkets are ubiquitous, which result in maladaptive responses, such as heart disease, high cholesterol, and obesity (Geher 2014).

Modified pictures and popular movies with slim women and men have significant influence on its audiences. Teenagers and young adults prioritize their physical appearance so high that they become malnourished or spend masses of money for unnecessary surgeries. Both the absence of images of slim women and men throughout *Homo sapiens'* evolutionary history and the social-behavioral phenomenon to imitate individuals with seemingly desirable traits exploit humans' evolutionary mismatch of environments (Ferguson et al. 2011).

Evolutionary mismatch theory may also explain the rise of the epidemic of clinical depression. Evolutionary psychologist, Stephen Ilardi, advocates for a lifestyle similar to those of earlier

humans. Actively participating in social relationships, getting daily exercise with a diet similar to the *Paleolithic diet*, being awake and outside in broad daylight while maintaining a proper sleep schedule, and being mentally engaged to minimize rumination comprise Ilardi's new therapeutic regime. Healthy diets, proper exercise and sleep, exposure to sunlight, and living in the present moment are painstakingly difficult to obtain in modern developed nations. The vast majority of clinically depressed individuals who participated in Ilardi's program reported to have obtained an overwhelming degree of success and recovery without the use of antidepressants (Ilardi 2010).

Although there are cogent instances of evolutionary mismatch when comparing the ancestral environments with those of developed nations, social scientists urge evolutionary psychologists to demonstrate the phenomenon in all nations and cultures. Universal behavior across independent cultures would elucidate evolutionary psychology's role on modern behavior.

Any two cultures are far from identical, but the variations between them are not completely random (Schmitt et al. 2016). Evolutionary psychology with the cultural and multicultural psychology perspectives provides viable predictions within esoteric cultures. Women with a waist-to-hip ratio of .7, for example, is rated as the most attractive by men from both developed nations and indigenous tribes (Singh and Young 1995; Buss 2015; Schmitt et al. 2016), which bolsters the hypothesis of universal behavior as evidence for a biologically evolved psychology.

Evolutionary Psychology and the Subdisciplines of Psychology

Any mental capacity or ability that *survives* and is passed down to the next generation, one way or another, is technically an *evolved* psychology. Evolutionary anthropologists and psychologists claim that human psychology is derived from early humans as hunter-gatherers (Cosmides and Tooby 1997), and despite that it was designed for prehistoric environments, it *survived* or *adapted* to modern environments. More simply, modern psychology is prehistoric psychology "but on steroids" (Pinker 2011).

Stimuli from contemporary cultures and environments act on the same biological frameworks that stimuli from ancient cultures and environments did. The difference between how the mind operated and functioned in hunter-gatherers and how it operates and functions in modern human beings is not due to a biological change; it is due to an environmental and cultural one. Reading, going to school, and living in large cities are examples of evolutionary novelties. Although many novelties engender admirable behaviors, many yield abominable ones.

It is a common misconception to view evolutionary psychology as a justification for malicious or any sort of behavior. Individuals who support this *naturalistic fallacy* fail to recognize that the study of evolutionary psychology can provide powerful insight of how to proactively control unwanted behaviors (Wilson et al. 2003). With the understanding of any complex system, one can do more than just control unwanted behaviors. The philosophy of evolutionary psychology can produce viable predictions of behavior within various branches of psychology. An adaptationist perspective will yield unasked questions that traditional psychologists neglect.

The *modularity hypothesis*, the position that the brain is like a computer with programs that are installed for various functions, is still at the center of debate within cognitive psychology. Evolutionary psychologists espouse the modularity hypothesis in a manner similar to why evolutionary biologists espouse that almost every characteristic of an organism specializes in a particular function (Cosmides and Tooby 1997). Certain cognitive traits and capacities develop at certain rates and are nonrandomly situated in specific locations of the brain (Caporael 2001). Cognitive traits do not arise from oblivion for no reason (Buss 2015; Barkow et al. 1995).

The cornerstone of human culture, language, is a truly universal attribute among *Homo sapiens*. A social species with the ability to express unlimited information can quickly dominate those without same ability. Evolutionary psychologists explain the origins of verbal language as an exaptation or by-product of human social nature and intelligence (Pinker 2010; Caporael 2001) that has

transcended into an adaptation. Traditional cognitive psychology does not refute that language has a biological basis, but it does assert that the capabilities for verbal language are primarily obtained through practice. The controversial *critical period*, the time when humans are most prepared to acquire verbal language skills, suggests that language can only be learned within a human's specific time window. With the fact that language is localized within Broca's area, the region of the brain associated with human speech, evolutionary psychology sits at the forefront of investigating the biological bases of verbal language (Pinker 2010).

Social psychology is a prime disciple of the SSSM. Cultural and social psychologists frequently claim that cultural norms and experience strictly shape human psychology; however, *culture* is not an adequate explanation for behavior. Moreover, explicating behavior via culture may be a redundant and even a stalling explanation (Barkow et al. 1995). Social psychology supports that committing altruistic acts are strictly motivated by intrinsic satisfactions. Ethology and evolutionary psychology, on the other hand, well explain and predict the instances of altruistic behavior.

Kin-selected altruism rests on evolutionary biological principles that can be observed in many nonhuman species. From a gene's perspective, putting oneself in harm's way in situations where the gene can continue to survive via its host's biological relatives sheds light on the unconditional nurture between biologically related organisms (Geher 2014). In low-risk or low-cost situations, humans are more likely to act altruistically toward friends, which can be reciprocated, whereas humans in high-cost situations are more likely to help their kin or family (Stewart-Williams 2007).

Life history theory may ultimately predict the development of the brain maturity and certain mental abilities (Figueredo et al. 2006), which is also subject to the study of developmental psychology. The onset of puberty and the relationship between infant mobility and fear of heights suggest that both bodily and mental changes are not completely random (Swanepoel et al. 2016).

Applying life history theory, a biological evolutionary theory, to developmental psychology may help social scientists learn when and how to intervene various behaviors.

Attachment is fundamental to the development of healthy social relationships. Both traditional and evolutionary developmental psychologists stress the importance of establishing interpersonal relationships on one's well-being and fitness. Renowned scientist, John Bowlby, examined the functions of the development of an unconditional attachment between an infant and caregiver. Bowlby (1982) recognized that many primates and mammals evolved behavioral-motivation systems to have both their physical and emotional needs met by a caregiver (Palanza and Parmigiani 2016). If these needs are met, individuals will develop a healthy and secure attachment style toward others; if not, individuals are likely to develop an insecure attachment style that could lead to severe issues within subsequent social and personal relationships.

Evolutionary psychology can also contribute to the field of personality psychology. Each of the Big Five personality traits (openness, conscientiousness, extraversion, agreeableness, and neuroticism) can be portrayed as a behavioral adaptation. Evolutionary theory hypothesizes that extraversion is rated as more attractive than introversion (Nettle and Clegg 2008). Not only was the hypothesis supported; it was also found that the more extraverted an individual reports to be, the more sexual partners that individual is likely to have (Buss 2015). Beyond personality traits, evolutionary psychology traces self-esteem, subjective well-being, and mental disabilities to their origins and uses. Additionally, the variation of personality characteristics across cultures is not due to chance, but is due to the environmental conditions (Schmitt et al. 2016).

Treating mental disorders like anxiety and depression is incredibly rare in indigenous tribes that are independent from other cultures, whereas developed societies treat mental disorders on a daily basis (Ilardi 2010). Evolutionary psychology poses unprecedented questions that gravitate around a variant of functionalism. Mania and periods of low energy and activity fluctuate with

the four seasons, which is a relationship that cannot be depicted without the evolutionary lens (Geher 2014). Most, if not all, psychiatric disorders are considered to be results of the mismatch between ancestral and modern environments. Clinical depression, among other mental illnesses, is now under immense scrutiny since the evolutionary perspective advanced depression treatments within clinical psychology (Buss 2015; Palanza and Parmigiani 2016; Ilardi 2010).

Conclusion

Psychology is, in a perspective, a branch of biology; however, psychologists and biologists are reluctant to inspect phenomena from the other domains. Established theories of evolutionary biology, such as sexual selection and life history theory, indirectly influence behaviors that take advantage of physical attributes and abilities. While the brain shelters the human soul, it abides by the laws of biological evolution.

Although cultural evolution complicates the means to observe evolved behavioral adaptations, by-products, and random effects, evolutionary mismatch theory disambiguates one from the others. Modern tools and technology facilitate many endeavors, yet their consequences accumulate to a seemingly incessant burden. Human psychology evolved from humans with the predominant occupation of hunting and gathering, yet the once adaptive traits betray our physical and mental health today. Whether or not culture is responsible for one's actions, it is not a cogent explanation of behavior.

Universal behavior across modern and indigenous cultures, like mating preferences and social altruism, is an evident support for psychology possessing a heritage. Despite that evolutionary psychology is mistakenly accused for justifying unwanted behavior, it has made prominent advances in cognitive, social, developmental, personality, and clinical psychology. With the adaptationist frame of mind that can be applied to, perhaps, all psychologies, evolutionary psychology cannot be sufficiently identified as a sub-discipline of psychology. Given that psychology

is a descendent of biology, evolutionary psychology is not an opposition of traditional psychology; it is a missing property of the study of mind and behavior, psychology.

How the Mind Works

Definition

A 1997 book by Steven Pinker.

Introduction

Steven Pinker's *The Language Instinct: How the Mind Creates Language* (1994) played a vital role in refuting many myths regarding the development of language abilities. Pinker argued against the behaviorist perspective that language acquisition was primarily or entirely the result of operant conditioning process and presented substantial evidence to attest to the fact that, despite its complexity, understanding and using spoken language is a relatively easy accomplishment for most children. Language acquisition is largely dependent on evolved psychological mechanisms, which result in a predictable developmental sequence of language abilities.

In *How the Mind Works* (1997), Pinker extends his work on language from *The Language Instinct* while simultaneously broadening the focus to include myriad other areas of psychology and cognitive science: vision and the senses, emotion and affect, ideology, sexual attraction and love, gender roles and identity, learning, judgment and decision making, social behavior, and much more. Pinker's expansion of his range of topics is necessary to address the goal of *How the Mind Works*: to attempt to explain the many functions of the mind, including those that are poorly understood, in evolutionary terms. Or, as Pinker himself puts near the end of his book, "To get you to step outside your own mind for a moment and see your thoughts and feelings as magnificent contrivances of the natural world rather than as the only way that things could be." (p. 563). The work is largely inspired by and uses the frameworks of cognitive psychology and evolutionary psychology, and Pinker highly utilizes the work of prominent evolutionary psychologists such as John Tooby and Leda Cosmides.

Main Assertions

Pinker's two main assertions in *How the Mind Works* are taken from cognitive and evolutionary psychology. First, Pinker utilizes the information processing metaphor from cognitive psychology/cognitive science, which posits that the human

mind is like a computer, which utilizes sets of algorithms (“modules” or “programs”) to process data and produce behavioral output. Second, Pinker asserts that these mental programs represent evolved psychological mechanisms that were crafted by natural selection to efficiently solve specific adaptive challenges: acquiring language, choosing mates, avoiding danger, etc. Pinker even uses an evolutionary framework to explain negative emotional states such as sadness, which may elicit social support when we need it most, and disgust, which motivates us to avoid contamination by potentially lethal pathogens. Because natural selection results in evolved psychological mechanisms that on average improve the odds of an organism passing on its genes, Pinker’s viewpoint explains why our minds are often predisposed to believe things that are untrue but that enhance our ability to survive and reproduce.

Conclusion

Toward the end of *How the Mind Works*, Pinker poses the question “[I]f the mind is a system of organs designed by natural selection, why should we ever have expected it to comprehend all mysteries, to grasp all truths?” (p. 563). Indeed, a mind that evolved to efficiently navigate the relatively small-scale social dynamics and primitive survival pressures of our early human ancestors should not be expected to easily grasp macroeconomic, geopolitics, or the mysteries of the cosmos.

Definition

An evolutionary approach to human behavior, and its outcomes, that attempts to understand the adaptation at the phenotypic level in a current ecological and social environment.

Introduction

Human behavioral ecology (HBE) is one of the major approaches in evolutionary behavioral sciences. HBE investigates adaptation of human behavior, and its outcomes, in a current environment in terms of the theory of fitness maximization. HBE covers a variety of research topics (the whole of life history, for example: foraging, livelihood, mating, reproduction, parental care, health, cooperation, and sociality), study subjects (people in traditional small-scale, pre-industrial, historical, and modern developed societies), and methodologies (ethnographic fieldwork, interviews, questionnaires, experiments, statistical analyses of secondary datasets, and mathematical models). This entry briefly explains HBE's trends, recent representative studies, and an integrated theory with closely related other fields, that is, evolutionary psychology (EP) and cultural evolution (CE).

Note that this entry uses different names for each academic discipline (like anthropology, psychology, or demography) just for convenience and never stick to the terms themselves.

Trends

This entry deals with the recent (since the mid-1970s) trends of HBE and does not refer to the whole history, such as Charles Darwin's huge contribution to the evolutionary understanding of human behavior (see Laland and Brown 2011 for detailed history). Around the same time as Edward O. Wilson's *Sociobiology: The new synthesis* in 1975, HBE came to be recognized as a powerful approach to evolutionary behavioral sciences. According to previous reviews (Nettle et al. 2013; Winterhalder and Smith 2000, see also invited commentaries to Nettle et al. (2013) in the same issue), HBE began especially from studies on foraging and production in hunter-gatherer populations and then grew with further investigations on resource distribution and reproduction in traditional small-scale societies (in addition to hunter-gatherers, horticulturalists, and agropastoralists). In these early phases, field anthropologists took leading roles.

Thereafter (since the mid-1990s), the proposition of studies on reproduction and that in industrialized

societies have been increased. In this later phase, researchers in not only anthropology but also other disciplines, such as psychology, demography, public health, and sociology, participate in HBE actively. In the light of evolution, HBE can provide a concise theoretical framework and ultimate explanations. One of the most epochal papers is Kaplan et al. (1995). This study conducted an interview survey at a driver's license center in New Mexico, USA, and collected reproductive and socioeconomic information on three generations (i.e., children, parents, and grandparents). Using this dataset, they analyzed a trade-off between children's quantity and quality, and the relationship between socioeconomic success and reproductive success. In the three-generation analyses, their sample did not maximize fitness (here, the number of grandchildren), while there were trade-offs between parental fertility and offspring socioeconomic status (see also Morita 2018 for a review). As well as Kaplan et al.'s pioneering study, statistical analyses of secondary datasets also contributed to the development of HBE. Rich demographic data of individuals are useful to test evolutionary hypotheses in human populations (e.g., Mattison and Sear 2016; Morita 2018).

Below, two representative studies published very recently are introduced. One is an achievement from a field survey in Africa and the other is a statistical analysis of longitudinal historical data in Europe. These two studies will show recent developments in HBE clearly.

Case Study 1: Children's Time Allocation and Schooling in Tanzania (Hedges et al. 2018)

In modern competitive labor and subsequent mating markets, acquiring high skills, knowledge, and experience during childhood should be critical to win the peer competition in the near future. This situation will favor reproductive strategy in which parents aim to have a small number of high-quality children. The large amount of parental investment in children's education is a principal driver of fertility decline (low birthrates), a paradoxical and puzzling phenomenon for HBE (e.g., Collieran and Snopkowski 2018).

Parental investment has strong effects on reproductive outcomes for both parents and children. However, how such parental attitudes influence children's time allocation and trade-offs between schooling and other activities were rarely investigated quantitatively. Hedges et al. (2018) conducted an interview survey in Tanzania where the socioeconomic modernization and demographic transition to low fertility are undergoing right now. They found that there existed several trade-offs in children's time allocation depending on their sex, age, and residential area (i.e., town or village, a proxy for modernization). For boys living in the village, there was a trade-off between time spent in education and that in farm work. For elder (14–19 years old) girls, especially living in the town, time for education decreased that for chores. They also showed that a robust trade-off appeared between schooling and leisure time. The economic and opportunity cost of education, sexual division of labor, and degree of modernization led to different patterns of trade-offs in time allocation of children in the region. These findings are valuable for deep understanding of reproductive strategies in a novel environment (in other words, socioeconomic contexts) that humans are facing at present.

Case Study 2: Temporal Changes of Grandmotherhood Patterns in Finland (Chapman et al. 2018)

In humans, many individuals other than mothers and fathers, such as grandparents, siblings, other kin, and also nonkin, participate in childcare. This reproductive system is called cooperative breeding (a narrow sense), communal breeding, or alloparenting (broader senses). Through evolutionary processes, the presence of helpers has facilitated human's shorter birth intervals than other great apes. In particular, it has been suggested that grandmothers make an immense contribution to grandchildren's care (but see Sear 2017 for the cross-context variation of kin effects on fertility).

In some (especially Western) countries, abundant parish registers from local churches are available and these resources of pedigree data are quite useful for HBE. Chapman et al. (2018) investigated how grandmotherhood patterns varied across the

demographic transition to low fertility and low child mortality by analyzing longitudinal data in Finland. Their dataset included detailed records of individuals' births, deaths, dispersal, marriages, and reproduction for up to 15 generations. The subjects were 66,160 grandchildren born between 1790 and 1959 and their 7,349 grandmothers. They analyzed changes of the grandmother-grandchild relationship over time and found that both the percentage of grandchildren who had grandmothers (maternal and paternal) at births and their shared time were increased during/after the demographic transition. This study revealed temporal changes of grandmothering for the past about 200 years and also provided further implications to interdisciplinary fields, such as biology (the evolution of family and alloparenting), demography (age structure changes in the population, due to fertility and mortality transitions), public health (post-reproductive longevity of grandmothers and its effects on social care), and sociology (family structure changes associated with modernization).

Integration with Evolutionary Psychology and Cultural Evolution

HBE has close connection with other evolutionary approaches to human behavior, EP, and CE (see Laland and Brown 2011 for details). EP sheds more lights on psychological mechanisms or decision-making algorithms underlying each observed behavior. EP assumes that humans have acquired psychological foundations in ancestral environments (the so-called EEA: environment of evolutionary adaptedness) and a current environment may much differ from the past ones. CE pays primary attention to cultural traits that can be inherited to the next generations independently of biological fitness in a genetic sense.

As well as HBE, EP, and CE seek evolutionary adaptation of human behavior (but not limited to behavior). However, EP and CE attempt to find it in different levels (i.e., not in observed behavior but in psychological mechanisms or nongenetic cultural transmission underlying behavior). Therefore, EP and CE will enable researchers to better understand (seemingly) evolutionarily maladaptive outcomes (e.g., fertility decline, child

abuse, and suicide). Environmental mismatches and maladaptive culture sometimes may result in behaviors that decrease reproductive fitness. Advanced integration of HBE, EP, and CE can enhance more holistic theories in evolutionary behavioral sciences (e.g., Morita 2018).

Conclusion

HBE explores adaptation of human behavior in a current environment. Since the 1970s, HBE has varied its main contents but grown definitely. In addition to “traditional-type” studies on foraging and resource distribution in small-scale societies, a number of “new-type” studies on reproduction in industrialized populations have been performed. Both fieldwork with unique perspectives and statistical analyses of secondary datasets are recent remarkable achievements. HBE contains a variety of research topics, study populations, and methodologies, which promotes further evolutionary understanding of human behavior. By integrating with EP and CE, maladaptive outcomes will also be explained better in future studies.

Definition

There have been significant changes in brain development, anatomy, and molecular biology over the course of human evolution.

Introduction

Modern humans are characterized by remarkable specializations of cognition, including a language that is rich in syntactic complexity and symbolic meaning, a nuanced understanding of the mental states of others, a strong motivation to share in pursuing joint goals, an ability to manufacture sophisticated tools, and an extraordinary capacity for cultural learning. What are the evolutionary changes in brain structure and molecular biology that underlie these cognitive faculties? A comprehensive understanding of human brain evolution requires data from multiple perspectives, incorporating information from fossils, archaeology, comparative neuroanatomy, and genetics.

Evolution of the brain in the human lineage

Compared to other primates and our earliest hominin ancestors, modern humans have very large brains. Weighing approximately 1,400 g on average, our brains are roughly three times bigger than those of other great apes and also significantly larger than expected for a primate of our body size (Jerison 1973; Martin 1990). Because great apes (chimpanzees, bonobos, gorillas, and orangutans) are the closest living relatives of humans, they provide the most relevant phylogenetic basis for comparison. More broadly, there are several mammalian species, including elephants, dolphins, and whales, that have bigger brains than humans in absolute size. Pilot whale brains have even been shown to contain more neocortical neurons than those of humans (Mortensen et al. 2014). But humans are the most extreme outlier from the typical mammalian brain-body size scaling relationship. Although the average adult human brain is only approximately 2% of body size, it consumes about 20% of the whole body's energy budget (nearly 400 kcal per day) due to the high level of activity of neuronal firing and signal transmission across synaptic connections (Kuzawa et al. 2014).

The hominin fossil record indicates that there has been a general trend over time for steadily increasing cranial capacity, accompanied by reorganization of cerebral morphology (de Sousa and

Cunha 2012; Falk 2012; Holloway 2015). The cranial capacity of hominin ancestors shows very gradual increase in brain size early in the evolution of the lineage, with a period of more accelerated growth within the last two million years since the origin of the genus *Homo* (Du et al. 2018). There are some notable exceptions to this apparent trend, however, such as *Homo naledi*, a southern African hominin which had a small cranial capacity of 460 ml at about 300,000 years ago (Holloway et al. 2018), and *Homo floresiensis* from the island of Flores in Indonesia, which had a cranial capacity of approximately 400 ml at 190,000–50,000 years ago (Falk et al. 2005). Additionally, it is apparent that evolution of endocranial morphology in fossil hominins has not always been tightly synchronized with brain size changes (de Sousa and Cunha 2012; Falk 2012; Holloway 2015). For example, there are differences in endocranial shape between recent modern humans and similarly large-brained close relatives, the Neandertals, and the earliest *Homo sapiens*. The endocranial shape of modern humans is more globular, or rounded, due to bulging of the parietal and lateral cerebellar regions (Bruner et al. 2003; Neubauer et al. 2018).

Several interrelated features of life history biology are associated with the large brains of modern humans, including elevated nutritional and metabolic requirements, slower development, a longer lifespan, and more involvement in raising offspring by fathers and grandparents to assist mothers (Sherwood and Gómez-Robles 2017; Hawkes and Finlay 2018). Also, likely due to obstetrical or energetic constraints on the timing of parturition (Rosenberg 1992; Dunsworth et al. 2012), a larger fraction of brain growth in humans occurs after birth compared to other primates (Halley 2017). This means that significant neurodevelopmental events that lay the groundwork for brain function, such the refinement of synaptic connections and myelination of axons, take place over a prolonged period of time in a rich social and ecological context (Petanjek et al. 2011; Miller et al. 2012; Bianchi et al. 2013). The plastic brains of our helpless human infants incorporate these experience as neuronal circuits are being constructed, paving the way for more elaborate cultural learning (Buřill et al. 2011; Sherwood and Gómez-Robles 2017).

Detailed comparisons of human brain anatomy to that of other primates, particularly chimpanzees, have shown that the association regions of the prefrontal, posterior parietal, precuneus, and temporal cortex involved in higher-order cognitive functions have become especially expanded (Buckner and Krienen 2013; Rilling 2014; Bruner et al. 2017; Mars et al. 2017; Smaers et al. 2017). These cortical regions also mature particularly late in development (Sakai et al. 2011; Fjell et al. 2015). Some have argued that change in the absolute and proportional size of the prefrontal association cortex is tightly correlated with corresponding changes in other brain areas (Barton and Venditti 2013; Gabi et al. 2016), whereas other analyses show that human prefrontal cortex is enlarged beyond what would be predicted from primate brain scaling trends (Smaers et al. 2017).

To some extent, evolutionary changes to human association cortex have involved differential expansion of regions that have clear and well-established homologs in other primates (Donahue et al. 2018). Notably, many regions of the prefrontal cortex, including Broca's language area, have been shown to be homologous among humans, great apes, and various other anthropoid species (Gil-da-Costa et al. 2006; Schenker et al. 2008; Wilson et al. 2015). Furthermore, cerebral hemispheric asymmetry is not entirely unique in human brain evolution, and seems to be an extension of trends that can be observed in other primates, especially great apes (Balzeau et al. 2011; Hopkins et al. 2015). Some other changes in human association cortex, however, appear to comprise proliferation of novel and functionally distinct areas. For example, data suggest that, compared to rhesus macaques, human intraparietal sulcus includes four additional motion-sensitive areas dedicated to processing of three-dimensional form in relation to motion (Orban et al. 2006). As a result, human parietal cortex might include more regions dedicated to processing of shape. Addition of these and other posterior parietal areas likely enhanced processing of visual and somatosensory information involved in manipulative abilities associated with tool production and handling (Stout and Chaminade 2007). More detailed comparative mapping of parietal cortex in great apes, however,

is needed to resolve whether the observed intraparietal sulcus organization in humans is truly unique or shared with our closest primate relatives.

In addition to changes in the size of neuroanatomical structures, it is also apparent that there has been significant rewiring of fiber tract connections in human brain evolution. Several of the long-range pathways that interconnect the association regions of the frontal, parietal, and temporal cortex with each other and to the cerebellum are differentially expanded in human brains compared to other primates (Rilling et al. 2008; Balsters et al. 2010; Hecht et al. 2015). These circuits, which include the arcuate and superior longitudinal fasciculi, are involved in language, tool making, and imitation. Furthermore, reward systems utilizing the neurotransmitter dopamine in the striatum have been reshaped, likely to increase attention to social signals and facilitate vocal learning. Notably, comparative molecular and anatomical examinations of the basal ganglia show human-specific increase in dopaminergic innervation of the medial caudate nucleus (Raghanti et al. 2016; Sousa et al. 2017), a highly interconnected region of the striatum that is involved in language production, among other functions.

The evolutionary changes in the genome underlying distinctive molecular and cellular process of human brain development have also been investigated extensively. These studies have shown how single nucleotide substitutions, gene duplications, and modifications that regulate gene expression have impacted fundamental aspects of human neurobiology. Uniquely human genetic changes increase cell proliferation as the brain is being formed or stimulate neurons to grow more complex dendritic branches with a higher number of synaptic connections (Enard 2011; Florio et al. 2017; Suzuki et al. 2018). One particularly striking case is the gene *SRGAP2*, which has a human-specific duplicate (*SRGAP2C*) that functions to increase the density of synaptic spines on dendrites (Charrier et al. 2012). Relatedly, analyses of RNA transcript level in brain tissues of humans and other species have revealed increased gene expression in the human brain compared to non-human primates, which is not evident in non-brain

tissue, such as the heart and the liver (Enard et al. 2002). These human-specific upregulated genes are enriched for functions including synaptic transmission and energy metabolism (Cáceres et al. 2003; Uddin et al. 2004; Somel et al. 2013; Muntané et al. 2015), supporting the idea that human brain evolution is characterized by molecular modifications to increase levels of neuronal activity (Preuss 2011).

Definition

Both copulation and sexual intercourse have been used to refer to penetrative, heterosexual sexual activity, that is: penile-vaginal sex. Here, however, the term “copulation” will refer to both penetrative (i.e., vaginal or anal sex) as well as nonpenetrative (e.g., oral sex) forms of intercourse that occur between same-sex and opposite-sex partners.

Introduction

Defining sex is – perhaps surprisingly – the subject of significant debate and disagreement in lay as well as scientific circles. Several works have investigated the ways in which individuals define “sex” or “having had sex” and have arrived at disparate findings, depending on when these attitudes are assessed (Rosenthal 2013), the age of the respondent (Sanders et al. 2010), and even how the question is asked (Peterson and

Muehlenhard 2007). This ambiguity is mirrored in the scientific community, where “copulation” and “sex” have been used to refer to exclusively intromission (i.e., penile-vaginal sex) as well as intromission between opposite-sex conspecifics and penetrative sex, oral sex, and manual stimulation of genitals that occurs within both same and opposite-sex pairings (Bailey and Zuk 2009). Herein, human copulation, colloquially referred to as “sex” or “sexual intercourse,” will adopt an inclusive definition, including (1) oral sex, (2) vaginal sex, and (3) anal sex. The various expressions and function(s) of human copulation will be explored through the review of psychological, cross-cultural, and phylogenetic evidence.

Human Copulation

There is considerable debate and disagreement when it comes to answering the following question: What is sex? When discussing human copulation, or “sex,” with a partner, individuals have many different definitions as to the nature of the sexual contact implied. Generally, individuals are most likely to consider penile-vaginal intercourse as “sex,” while considerable disagreement appears with considerations of anal intercourse, oral sex, manual genital contact, and kissing

(Peterson and Muehlenhard 2007; Sanders and Reinisch 1999). The nature of the lay disagreement as to the classification of nonintromission sexual contact as “sex” seems to depend on several factors, including when these attitudes are assessed. As demonstrated in Fig. 1, more recent college student samples are *less likely* to define oral sex and manual genital contact as “sex” compared to college student samples assessed 20 years ago (Rosenthal 2013).

This difference in lay definitions of “sex” is also represented as an age difference, wherein men aged 18–29 are less likely to define oral sex and manual genital contact as “sex,” compared to men over the age of 30 (Sanders et al. 2010). Interestingly, the same cross-sectional study of definitions of “sex” found that all men *but* those in their oldest age group (65+) were significantly more likely to indicate that anal sex was defined as “sex” (Sanders et al. 2010). All of these works have used a similar approach when assessing disagreement as to the definition of “sex,” that is, asking participants if, after engaging in these various behaviors with a partner, they would say that they have “had sex” with that partner. In other words, these studies have all relied upon a methodology wherein they ask participants if various sexual behaviors “count” as sex. However, this methodology involves the implicit assumption that participants have clear (that is, not

Human Copulation, Fig. 1 The percentage of males and females that indicated that they would “say you ‘had sex’ with someone if the most intimate behavior you engaged in

was . . . ?” (Sanders and Reinisch 1999, p. 276; figure from Rosenthal 2013)

contradictory) definitions of what contact constitutes “sex.” Conclusions about how laypersons define “sex” may change if these attitudes are assessed in a manner which allows for the representation of uncertainty.

Work does suggest that the way in which participants are asked to define sex can affect the definition of sex that they provide (Peterson and Muehlenhard 2007). Specifically, Peterson and Muehlenhard (2007) asked participants to share experiences which were “almost but not quite. . .” or “just barely qualified. . .” as sex and thereby employed a methodology that allowed for representations of uncertainty or ambiguity in definitions of sex. Activities that “almost but not quite. . .” fit participants’ definitions of sex included brief or partial intromission, genital to genital contact without penetration, oral sex, and manual genital stimulation. Interestingly, these same activities were represented (albeit, to a lesser degree) as behaviors that “just barely. . .” fit participants’ definitions of sex. Participants explained that these nonintromission types of sexual contact “fit” within their definitions of sex because they contained what participants perceived to be other, critical defining features, such as genital contact, orgasm, “an exchange of fluids,” sexual arousal, and/or nudity. Taken together, it seems as though individuals have an overwhelming tendency to define sex/copulation as intromission, while expressing some uncertainty as to whether or not other types of genital contact such as oral sex, anal sex, and manual genital contact fit within this definition – among other factors (such as age, the specific ways in which definitions of sex are elicited from participants, etc.) it seems as though these definitions depend upon the *anticipated consequences* of labeling a specific type of sexual contact as “sex.” Specifically, when the consequences of labeling a specific type of sexual contact as “sex” are negative, individuals’ are more likely to label these experiences as “not quite sex” (Peterson and Muehlenhard 2007). For example, some individuals reported a motivation to define sexual contact with a same-sex partner as “not quite sex” in order to preserve their identity as heterosexual.

Disagreements as to the definition of copulation/sex are also present in the scientific community, where “copulation” and “sex” have been used to refer exclusively to intromission (i.e., penile-vaginal sex) as well as penetrative sex, oral sex, and manual stimulation of genitals that occurs within both same *and* opposite-sex pairings (Bailey and Zuk 2009). Studies of copulation in nonhuman primates often define copulation as sexual contact between opposite-sex conspecifics that *must* include intromission. Alternatively, comparative studies of sexual activity and contact between same-sex pairs have defined a variety of activities between same-sex conspecifics (e.g., oral sex, manual stimulation of genitals) as “copulation” (Bailey and Zuk 2009). The following evolutionary analysis of human copulation will adopt the latter, more inclusive definition, including (1) oral sex, (2) vaginal sex, and (3) anal sex. These various expressions and function(s) of human copulation will be explored through the review of psychological, cross-cultural, and phylogenetic evidence.

Oral Sex

Oral sex can be classified as either the stimulation of the female genitals (*cunnilingus*) or the male genitals (*fellatio*) with the mouth. The incidence of oral sex has been steadily increasing in the United States, and recent estimates indicate that over 80 % of individuals over the age of 20 have engaged in oral sex (85.4 % of men and 83.2 % of women; D’Souza et al. 2014). While oral sex is overall a very common form of copulation, individuals that are most likely to have engaged in oral sex are White men and women, individuals under the age of 60 (see Fig. 2), and individuals that have attended college (Baumeister 2001).

Evolutionary analysis of a given behavior, cognition, or affect typically follows one of the two paths of inquiry: (1) from form to function or (2) from function to form (Buss 1995). The former refers to the process of identifying a particular behavior of interest and searching for the adaptive problem for which that particular behavior may have been preferentially selected and perpetuated; in other words, what is the function of this behavior? The latter refers to the process of identifying a

Human Copulation, Fig. 2 The percentage of individuals (by race, age, and sex) that have engaged in oral sex and have engaged in oral sex proximate to their age at sexual debut (Figure from D’Souza et al. 2014)

particular adaptive problem of interest and searching for the behavior, cognition, or affect that might have solved that adaptive problem in ancestral environments; in other words, what psychological mechanism might have evolved to address this problem? Therefore, an analysis of a given behavior of interest – oral sex – will take the following form; what is the function of oral sex?

Oral sex has long been colloquially understood as a form of sexual contact that often serves as a substitute for other forms of sexual contact during one’s sexual debut (Duberstein Lindberg et al. 2008). As Duberstein Lindberg puts it, “There is a widespread belief that teens engage in nonvaginal forms of sex, especially oral sex, as a way to be sexually active while still claiming that technically, they are virgins” (Wind 2008). Indeed, oral sex is more common among teens than vaginal sex, and teens perceive oral sex to be less likely to precipitate many negative emotional and social outcomes, compared to vaginal

sex (e.g., less likely to get them into trouble, cause them to feel guilty or bad about themselves, less likely to conflict with their ethical, religious, or moral values; Halpern-Felsher et al. 2005). However, recent work suggests that oral sex often closely corresponds with the initiation of other types of sexual contact (including vaginal sex), rather than serving as an alternative for these other types of sexual contact (Duberstein Lindberg et al. 2008). Findings from a national survey indicate that the proportion of teens and young adults that engage in oral sex *before* other forms of sexual contact (26 % of females and 24 % of males) is strikingly similar to the proportions of teens and young adults that engage in oral sex *after* other forms of sexual contact (27 % of females and 24 % of males; Copen et al. 2012). It seems as though oral sex is common in both teens and adults but does not serve the function of initiating sexual activity or delaying other forms of sexual contact.

Comparative analysis of a particular behavior – such as oral sex – is often illuminating when determining the evolutionary function and adaptive importance of that behavior. Phylogenetic evidence, comparing the prevalence and function of a behavior in other species, supports the proliferation of an adapted behavior through generations of selection pressures. Oral sex is quite common in nonhuman animals, appearing in bonobos, stump-tail macaques (Chevalier-Skolnikoff 1974), lemurs, and orangutans. In nonhuman primates the function of oral sex is often affiliative between same-sex conspecifics. For example, observations of oral-genital contact in male stump-tail macaques suggests that such contact is most likely to occur between an adult male and a juvenile that has not yet reached sexual maturity, in the context of other positive, affiliative behaviors (such as grooming, carrying, and other parental care; Chevalier-Skolnikoff 1974). Also, the frequency of same-sex oral-genital contact between primates of disparate age suggests that this contact likely serves an educational function, critical to subadult primates' sexual development (Gray and Garcia 2013). Alternatively, it is possible that oral sex in nonhuman animals is simply reflexive, a response to attractant pheromones secreted near the genitals. In nonhuman animals, there is little consensus as to the function of oral sex, but the behavior may serve the complex function of assisting in the sexual development of subadults or fostering social ties between same-sex conspecifics.

Recent work has illuminated three potential functions of oral sex in humans (Pham and Shakelford 2013) – which, unlike other types of sexual contact (i.e., kissing), is a practice that is quite common cross-culturally – (1) the detection of rivals' semen, (2) the increase of partner's relationship satisfaction (and thereby, fidelity), and (3) the facilitation of sperm retention. The first proposed function of oral sex in humans, the detection of rivals' semen, is detailed in the *infidelity-detection hypothesis* that suggests cunnilingus may allow heterosexual males to test for the presence of rival semen in the vulva and therefore determine (at least in part) the sexual fidelity of their current mate. If cunnilingus serves this

infidelity-detection function, one would expect that these concerns would be particularly great during female peak fertility (when the likelihood of conception is greatest); indeed, nonhuman animals display more frequent oral-genital stimulation during female's peak fertility and humans indicate that the odor of vaginal secretions during peak fertility is more pleasant, compared to secretions during low fertility (Doty et al. 1975). Furthermore, men that are at a greater risk of experiencing sexual infidelity (operationalized as having a partner high in sexual and physical attractiveness) are more interested in performing oral sex and perform oral sex for longer durations than those with lower risks of experiencing sexual infidelity on part of their heterosexual partner (Pham and Shakelford 2013).

The second proposed function of oral sex – that it increases partner's relationship satisfaction – is partially supported throughout literature exploring the relationship between sexual satisfaction and relationship satisfaction. Frequency of oral sex has been repeatedly linked to sexual satisfaction, in same-sex and opposite-sex couples. Oral sex seems particularly important for the sexual satisfaction of individuals in same-sex couples, as lesbians report oral sex as their most-preferred technique for achieving orgasm and oral sex has been found to be the most-frequently engaged in sexual contact for gay men (Ekstrand and Coates 1990). What seems clear from this work is the relationship between oral sex and sexual satisfaction – the relationship that is more contentious in the literature is that between sexual satisfaction and relationship satisfaction.

Evident in the literature are *both* strong correlations between sexual satisfaction and various indicators of relationship satisfaction, such as overall satisfaction with one's marriage, satisfaction with one's dating relationship, and feelings of love and commitment, *as well as* longitudinal works indicating that relationship satisfaction and sexual satisfaction seem to change concurrently (Sprecher 2002). However, these findings are qualified by works which have failed to demonstrate strong evidence that changes in relationship satisfaction can account for or explain changes in sexual satisfaction or that changes in

sexual satisfaction can explain observed changes in relationship satisfaction (Byers 2005). Instead, it seems as though the relationship between sexual satisfaction and relationship satisfaction is mediated by the quality of communication in an intimate relationship (Byers 2005) and the similarity of sexual desire between partners in an intimate relationship (Davies et al. 1999). Overall, it seems as though oral sex can facilitate greater sexual satisfaction in both same-sex and opposite-sex mateships, but evidence providing a direct causal link between sexual satisfaction and relationship satisfaction is lacking.

The third proposed adaptive function of oral sex in humans – the facilitation of sperm retention – has received support in literature exploring the relationship between cunnilingus and the experience of female orgasm. Originally termed the *Upsuck Theory* by Masters and Johnson, recent work indicates that the experience of female orgasm (and the associated release of oxytocin) is associated with uterine contractions that act as a peristaltic pump, promoting the travel of sperm and other fluids in the reproductive tract towards the oviduct (Zervomanolakis et al. 2009). Therefore, if a female experiences orgasm during a heterosexual encounter, the likelihood of conception is promoted as the experience of female orgasm decreases the distance that must be traveled by spermatozoa to reach the ovum. Using both objective and subjective estimates of sperm retention (that is, sperm retained in the reproductive tract following penile-vaginal copulation), Baker and Bellis (1993) find that female orgasms occurring within a specific time window relative to male ejaculation (between 1 min before male ejaculation to 45 min after male ejaculation) increased the amount of sperm retained in the reproductive tract. This sperm retention theory appears to be relevant only to penile-vaginal copulation, rather than the current behavior of interest – oral sex. However, the likelihood of experiencing female orgasm through penile-vaginal copulation alone (that is no clitoral stimulation with the hands or the mouth, etc.) is quite low. Data from a national survey suggests that the likelihood of experiencing female orgasm during penile-vaginal copulation is dramatically

increased (from around 12 % to around 32 %) if oral stimulation of the clitoris (e.g., oral sex) occurs (Richters et al. 2006). Therefore, the likelihood of retaining sperm in the reproductive tract and the travel of spermatozoa and seminal fluid to the oviduct are both facilitated by the female orgasm, which is more likely to occur when the clitoris is stimulated, particularly via cunnilingus.

Vaginal Sex

Vaginal sex refers to penetrative copulation, which can be classified as the penetration of the vagina with the penis (penile-vaginal copulation). Contrary to contemporary rhetoric, the age at which heterosexual individuals initiate penile-vaginal copulation has been increasing in recent years; in 1995 around 20 % of young adults reported initiating penile-vaginal copulation before the age of 15, while estimates from 2008 indicate that only 11 % of females and 14 % of males report initiating penile-vaginal copulation before the age of 15 (Finer and Philbin 2013). Recent estimates indicate that the average age of penile-vaginal sexual debut is 17 years of age in the United States, with the likelihood of initiating penile-vaginal copulation dramatically increasing for both males and females after the age of 16 (see Fig. 3). The age of penile-vaginal sexual debut varies dramatically cross-culturally, with 40 % of Brazilian males and over 50 % of Bangladeshi females initiating penile-vaginal copulation before the age of 15 (Wellings et al. 2006). Penile-vaginal copulation is the most *common* form of sexual contact in heterosexual couples (98.5 % of couples surveyed experienced penile-vaginal copulation during a 21-day span; Hurlbert et al. 1993) and is reported to be the most *pleasurable* form of sexual contact in heterosexual males and females.

Vaginal sex can take many forms in primates, including (1) male on top, female supine (*ventro-ventral position*), (2) female on top, male supine (*ventro-ventral position*), (3) rear entry (*dorso-ventral position*), (4) inverted rear entry (*inverted dorso-ventral position*), and (5) side by side (*latero-lateral position*). The ventro-ventral position of vaginal sex, with the male on top, female supine (i.e., “missionary position”) is by

Human Copulation,

H

far the most common among humans (Gray and Garcia 2013) and has even been demonstrated to be common across cultures, appearing in the Alorese, Hopi, Marshallese, Tikopia, Balinese, among others (Dixon 2012). While occurring less frequently in other primates, orangutans, bonobos, and gorillas also engage in ventro-ventral vaginal sex, both with the male and with the female on top (Dixon 2012); some researchers hypothesize that this face-to-face copulatory posture evolved as primate intelligence increased, which gave way to variations in copulatory postures (specifically, variations from the dorso-ventral “norm”). Also, this face-to-face copulatory posture facilitates communication between opposite-sex conspecifics during vaginal sex, and such eye contact can be used to assess interest in sexual contact (Dixon 2012); indeed, eye contact has been demonstrated to be used as a method of communicating sexual intent. However, ventro-ventral vaginal sex with the male on top, female on bottom has been associated with low female sexual satisfaction and female difficulty achieving orgasm (Rosenthal 2013), as this position does not afford the female control over the depth, speed, or angle of intromission and often does not stimulate the clitoris. Variations

on the ventro-ventral position that involve manual stimulation of the clitoris *are* associated with a greater likelihood of females achieving orgasm during vaginal sex. It is important to note that it is uncommon for females to achieve orgasm when engaging in penile-vaginal copulation alone, that is, without additional clitoral stimulation orally or manually (“vaginal orgasm”; Gray and Garcia 2013). There is some evidence to suggest that the vaginal orgasm might play a role in mate choice, wherein longer penises are associated with a greater likelihood of achieving female vaginal orgasm and females that report a preference for longer penises are more likely to experience vaginal orgasms (Costa et al. 2012). These differences in orgasm outcomes might create a selection pressure favoring longer penises, particularly for females that experience vaginal orgasm.

Dorso-ventral copulatory positions (i.e., “doggie style”), less common but still preferred among male and female humans, are much more common among nonhuman primates. These positions allow the, typically larger, males to remain standing, while the female crouches on all fours. In primates the dorso-ventral copulatory position is often accompanied by the use of the feet (termed the “leg lock” position) or the hands to restrain the

female, particularly common during long duration vaginal sex (between 15 and 35 min; Dixon 2012). Importantly, the dorso-ventral copulatory position allows the males to retain a grip on tree branches with their prehensile tails and/or their feet. A fascinating variation on the dorso-ventral copulatory position is the inverted dorso-ventral position, wherein both the male and female primate are suspended, upside-down, by a tree branch. This position, common in the slow loris, slender loris, and the aye-aye, is thought to provide protective benefits, allowing the partners to hide during copulation and to quickly drop from their tree limb if disturbed or pursued by a predator (Dixon 2012).

As above, evolutionary analysis of a given behavior, cognition, or affect typically follows one of the two paths of inquiry: (1) from form to function or (2) from function to form (Buss 1995). Again, an analysis of the given behavior of interest – vaginal sex – will take the following form; what is the function of vaginal sex? There are two prevailing explanations as to the function of human vaginal sex, (1) (the somewhat obvious adaptive function) the production of offspring and therefore the proliferation of one's genes in future generations and (2) the increase of partner's relationship satisfaction (and thereby, fidelity). The former function refers to the fact that in the Environment of Evolutionary Adaptedness (EEA) for humans (roughly 10,000 years ago) – a time characterized by significant selection pressures in the environment which provided significant advantages in survival and reproduction for certain members of a species, with specific traits – modern medical technologies which enable individuals to conceive in the absence of penile-vaginal copulation were not available. Therefore, the production of offspring depended entirely upon fertilization as a result of penile-vaginal copulation between opposite-sex conspecifics. The necessity of sexual behavior (such as vaginal sex) for the survival and perpetuation of one's genes has likely produced natural rewards for engaging in such behavior, such as the production and release of neurotransmitters that produce feelings of desire and pleasure (e.g., dopamine and serotonin) in the nucleus accumbens and the

ventral tegmental area in the midbrain. Sexual behaviors are a “natural reinforcer” along with other behaviors that have been historically critical for survival and reproduction, such as eating, drinking, and seeking social connectedness. Activity in specific pathways of the brain (e.g., the nucleus accumbens and the ventral tegmental area) *rewards* individuals for and *motivates* individuals to engage in behaviors – like vaginal sex – which have been critical for the perpetuation of genes into subsequent generations. Put simply, were it not for the existence of vaginal sex and a desire to engage in vaginal sex, the human species would not continue to exist.

The second proposed function of vaginal sex – that it increases partner's relationship satisfaction and fidelity – is partially supported throughout literature exploring the relationship between sexual satisfaction and relationship satisfaction. As mentioned above, the existence of a *direct* causal relationship between sexual satisfaction and relationship satisfaction is somewhat contentious; however, the use of vaginal sex to maintain a long-term bond between mates is supported in both the human and nonhuman animal literature. Among nonmonogamous species of primates, such as lemurs and chimpanzees, almost all of their vaginal sex takes place during periods of female peak fertility, ovulation (Gray and Garcia 2013). Therefore, one might infer that in these nonmonogamous species, vaginal sex serves the primary function of producing offspring and that vaginal sex is motivated by cues indicative of female receptivity. These cues can be detected by scent or sight; male tamarins display increased erections and mounting behaviors when exposed to the scent marks of an ovulating female tamarin and vaginal sex increases in frequency while female bonobos display a swollen perineum, which is indicative of female ovulation. It is important to note that while these cues have evolved to signal times of peak fertility to sexually mature males and therefore motivate vaginal sex behaviors, the accuracy of these cues is a matter of some debate. According to the *graded-signal hypothesis*, in nonmonogamous species that live in multi-male, multi-female groups, signals of ovulation vary in their strength to indicate

variations in the probability of conception (Nunn 1999). For example, sexual swellings would vary in terms of their size with their largest expression indicative of the greatest probability of conception. This type of variable signaling provides benefits to both males and females of nonmonogamous species; it allows the males to preferentially engage in vaginal sex with fertile females, and it provides a sufficiently wide window of *possible* ovulation (i.e., “graded”) to produce paternity uncertainty – if males in these multi-male, multi-female social groups are unsure as to which offspring are their genetic relatives or that of their rivals, they will be less likely to engage in infanticide.

Alternatively, in monogamous species, such as gibbons and siamangs, vaginal sex (while taking place relatively infrequently) does take place during periods of female infertility (e.g., when a female is currently pregnant; Gray and Garcia 2013). There are several physical markers that indicate a species evolved to engage in monogamous mating in the context of long-term pair bonds – such as small testicles (indicative of infrequent sperm competition) and low sexual dimorphism (indicative of *similar parental investment* provided by males and females, and relatively infrequent male physical competition for access to mates). In fact, some scholars argue that monogamy may have evolved, in part, to solve the adaptive problem of producing and caring for offspring that require significant investment; for instance, due to a long juvenile period or ecological constraints that make acquiring enough resources to produce healthy offspring difficult without male–female cooperation.

It is possible that the vaginal sex that takes place during periods of female infertility, observed in gibbons, siamangs, and many monogamous bird species (Eens and Pinxten 1995), may serve a function of increasing relationship satisfaction and protecting against threats to the fidelity of the mateship. For example, female sterlings have been observed courting and initiating copulation with males whom were seeking the attention of other females even after they have laid fertilized eggs (Eens and Pinxten 1995). Humans also engage in several mate retention tactics,

including enhancing one’s appearance to appear more attractive to one’s partner and engaging in more frequent sexual contact, in response to perceived threats to their relationship. Interestingly, both men and women have reported faking orgasm during vaginal sex in order to increase their partner’s satisfaction (Muehlenhard and Shippee 2010) and women are more likely to fake orgasm during vaginal sex when they perceive that their relationship may be at a greater risk for experiencing partner infidelity and defection.

Anal Sex

Anal sex refers to penetrative copulation, which can be classified as the penetration of the anus with the penis (penile-anal copulation). While often colloquially assumed to be prevalent in gay sexual relationships, 20 % of gay men report never experiencing anal sex (Laumann 1994). Furthermore, the incidence of anal sex has been steadily increasing among heterosexual couples in the United States, with estimates (of having “ever” engaged in anal sex with an opposite-sex partner) increasing from around 20 % in 1995 to approximately 36 % in 2013 (Chandra et al. 2013). While anal sex is overall a relatively uncommon form of copulation, individuals that are more likely to engage in anal sex are typically those that report higher levels of education and lesser religiosity (Baumeister 2001). Interestingly, women report anal sex as being their least preferred and the least satisfying type of sexual behavior (Hurlbert et al. 1993). While oral sex is reported as being the most preferred and most frequently engaged-in type of sexual behavior by gay men, anal sex is still a relatively frequent type of sexual contact in male same-sex couples; 75 % of men reported engaging in the “insertive role” while 81 % reported engaging in the “receptive role” (Laumann 1994).

Anal sex in the primate world is rare, and often occurs during isosexual encounters (male-male mounting and intromission; Dixon 2012). The male same-sex mounting and anal sex which take place in nonhuman primates is proposed to serve a developmental function – occurring frequently in juveniles and decreasing in frequency

as the primate reaches sexual maturity – and is proposed to be maintained and motivated by the pleasurable sensation associated with engaging in anal sex from the “insertive role” (Dixon 2012). This type of male same-sex anal intromission has been observed in orangutans, stump-tail macaques (Chevalier-Skolnikoff 1974), and rhesus monkeys, among others. As discussed relevant to oral sex above, same-sex sexual contact via anal sex in nonhuman primates likely serves the adaptive function of facilitating sexual development (Chevalier-Skolnikoff 1974). Interestingly, some documented cases of anal sex between same-sex conspecifics do not seem to be developmental and transitory in nature; in the case of two male rhesus monkeys raised in captivity, the two monkeys were capable of successfully mounting and achieving ejaculation during mating with a female, but demonstrated a preference for social and sexual contact with their male partner when given the option to interact with a female.

Conclusion

In the current discussion of human copulation, it has been demonstrated that the definition of copulation or “sex” is the topic of significant debate and disagreement, both within lay and scientific circles. Overall, one’s individual definition of “sex” or “having had sex” seems to depend on when these attitudes are assessed (Rosenthal 2013), the age of the respondent (Sanders et al. 2010), and how the question is asked (Peterson and Muehlenhard 2007). This ambiguity in the scientific community may be indicative of a transition away from heteronormativity, where “copulation” and “sex” have historically been used to refer exclusively to penile-vaginal sex but are now adopting more inclusive definitions which can capture partnered sexual contact between same-sex conspecifics (Bailey and Zuk 2009).

Taken together, human copulation in the form of oral sex is becoming increasingly common and likely serves the adaptive function of promoting social connectedness (in nonhuman primates) or is simply a reflexive response to appetitive vaginal

secretions. Furthermore, oral sex in humans may serve the adaptive function of allowing for the detection of infidelity, increasing relationship satisfaction, and facilitating sperm retention (Pham and Shakelford 2013). Vaginal sex is the most common and most preferred form of sexual contact between heterosexual couples. While dorso-ventral forms of vaginal sex are most common in the primate world, the appearance of ventro-ventral (face-to-face) vaginal sex in some primates (including humans) may have evolved to facilitate communication or is simply indicative of increasing species intelligence. Vaginal sex likely serves many functions, including the propagation of one’s genes into subsequent generations, increasing relationship satisfaction, and increasing the likelihood of partner fidelity. Anal sex, while relatively uncommon in the primate world, is becoming increasingly common in heterosexual human mateships (Chandra et al. 2013). It likely serves affiliative and relationship maintenance functions in humans, as well as functions relevant to sexual development in nonhuman primates (Chevalier-Skolnikoff 1974). Overall, it is clear that human copulation, in its many forms, serves important functions for developing and maintaining social connections, sexual development, and satisfaction in intimate mateships. Many of these behaviors have been present throughout evolutionary history, as evidenced by the many copulatory behaviors shared with nonhuman primates. Future work will continue to illuminate the nature of the changing social and sexual world and the implications these changes might have given the ways in which evolution has shaped humans into sexual creatures.

Definition

The process of social and cultural processes whereby one attempts to gain another as a mate.

Introduction

Courting as we know it has gone through a drastic change in the last century, with an almost insurmountable level of change in the past decade due

to technology. The word courting itself is old fashioned, bringing images of ice cream socials in the 1950s – now we commonly use words like dating. Once upon a time, and currently in some cultures, a man and a woman did not choose to spend their lives together, their bond was chosen by parents or other authority figures. When mateships are decided upon by outside people, there was/is no courting necessary. In modern times (with some exceptions), this tradition of having a mate chosen by an outside party has gone by the wayside and has been replaced with courtship – a period of time wherein a couple gets to know one another, often wherein one person (usually the male) competes for the attention of the other.

Courting, or dating, comes down to a much more simple concept than it immediately appears – courting and dating is the human equivalent to the procurement of a mate for reproductive purposes. Courtship, or dating, is the modern human equivalent to sexual selection and the displays that certain species engage in when seeking a mate. Much of evolutionary psychology is focused around the attainment of a mate – how it is done for different species, how the attainment of a mate has changed over time, and what sort of variables affect mate attainment.

Parental Investment

Humans are no exception to the rules put forth by Trivers’ (1972) theory of Parental Investment – the sex which possesses a larger minimum investment in offspring is the sex that chooses a mate, while the sex which has a smaller minimum investment in offspring competes for access to mates. In the context of humans, like most species, females hold the larger minimum investment (9 months gestation and labor at the absolute minimum), thus they are the sex that gets to choose mates, while males (whose minimum investment is the ejaculation of sperm) hold the smaller minimum investment is the sex that must compete for access to the females through intrasexual competition. What all of this investment and competition information adds up to is

quite simple: men compete more for access to women, while women are choosy in picking a man to mate with. In dating terms, this simply goes together with the generally accepted gender roles associated with human dating – men pay for meals and compete with access with other males for female attention. A clear and concise way to understand and remember courting practices and their ultimate goals is to realize that, especially in the animal kingdom (particularly with non-human species), courting is merely a series of events that must occur in order for copulation to be allowed, agreed upon, or desired.

Human courting varies dependent on historical context, religion, cultural norms, and family norms. Currently, in a Western context with a secular religious emphasis, males and females seek each other out for dates and exhibit a long courting period before (if) marriage happens. Previously, males and females used courting as a prerequisite of sorts for marriage – courting was used to determine whether a male and female were a good fit for marriage, marriage being the ultimate, paramount goal. Now, it is common for humans to date for the sake of dating, without marriage as an ultimate or proximate goal in mind. It is particularly interesting that, while the goal of dating may have gone from ultimate (marriage is the point) to proximate (dating for the sake of dating), the gender roles devised by biological differences such as minimum parental investment have not changed – even if a man is not courting a woman to test her for marriage material, he is still the one seeking and competing, while she is the one who makes decisions about whether or not she wants to date the male, and what type of relationship she is willing to have with him (short-term – sexual, or long-term – committed).

Sexual Intent

Another important variable when discussing human courting is perceived sexual intent – the “friendzone” is somewhat of a joke on sitcoms like *How I Met Your Mother* and *Raising Hope*, often discussed more seriously in the bowels of

the internet where men who perceive themselves as “nice guys” lament over the “friendzone” and how they are always placed in it despite their best efforts. The “friendzone” is a fictitious place where men go when they befriend a woman and take too long to make their move, thus appearing as nothing more than a friend in the eyes of a female. The friendzone is mentioned as an easy way to understand perceived sexual intent. When males and females begin to court one another, in modern times where women and men are friends (and modern cultures, where women are allowed to be in the presence of a man without a male relative with her for protection), there is not always clear sexual intent. The question “could this individual only want to be my friend, or are they interested in a copulatory relationship with me” is often raised in the minds of individuals beginning a courtship. One can plainly see how a misunderstanding of sexual intent could lead to trouble: from mere discomfort between the two individuals to the possibility of sexual assault or misconduct (see subsection below).

Operational Sex Ratio

There are numerous variables that affect dating behaviors. One such variable that drastically changes behavior in dating is operational sex ratio (OSR). Operational Sex Ratio is the ratio of reproductively viable males to females in a given mating market. It is important to understand the logistics of mating markets in order to better understand mating and dating behaviors. Operational sex ratio generally is divided into three major categories: equitable, wherein there are an even number of reproductively viable males and females in a given market; female disadvantaged/male advantaged, wherein there are proportionally more females than males in the mating market; and female advantaged/male disadvantaged, wherein there are proportionally more males than females in the mating market. It makes sense from a simple supply and demand point of view that operational sex ratio would affect dating habits and behaviors. Males and females have different wants and desires, and it

stands to reason that male wants and desires would be put ahead of female wants and desires in a male advantaged/female disadvantaged ratio, and vice versa. Because of this, we do see behavioral changes in courtship and dating across different OSRs.

Conclusion

Human courting is an incredibly complex process that has evolved with us over hundreds of thousands of years. Many factors can affect the outcome of a relationship between two individuals, especially Paternal Investment and Operational Sex Ratios in their immediate environment. Though humans display indices of Parental Investment our courting behavior can still be incredibly plastic depending on a multitude of variables, including environmental factors.

Definitions

Deception is notoriously difficult to define given that there are so many forms across human and nonhuman animals (Mitchell 1993). Here, we define deception as the intentional or unintentional misrepresentation of information. This misrepresentation can be conscious or unconscious and may serve a multitude of purposes including (but not limited to) survival (e.g., physical defense), resource acquisition (e.g., acquiring food or resources), or increased inclusive fitness (e.g., reproductive advantages).

Introduction

Deception is common in human interactions (Kashy and DePaulo 1996). It can be intentional such as in the case of lying, self-presentation, or withholding important information. Deception may also be unintentional or unconscious, such as in the case of self-deception (e.g., von Hippel and Trivers 2011). Deception may stem from

good intentions or a desire not to harm, or it may come from a place of selfishness or malevolence.

In the animal kingdom, deception is often used for survival. Some researchers have argued that survival of primates is calibrated on deception and that “Machiavellian intelligence” is required for survival (Byrne and Whiten 1989). Despite its benefits, deception also poses risk. To deceive and fail can pose fitness costs in the form of ostracism or death. To deceive and succeed could mean fitness enhancement.

Although a tremendous amount of research and theoretical attention has been paid to the evolution of cooperation and reciprocal altruism in modern society (Trivers 1971), players in a cooperative society may not merely fit a cooperator vs. cheater distinction. Instead, some deceptive individuals may engage in cooperation for long periods of time in order to cultivate trust and the appearance of cooperation. This cultivation of trust, however, may ultimately be in the service of large-scale defection. In this way, individuals in cooperative societies might be better categorized as cooperators and cheaters.

Deception and defection are pervasive in modern society. At the corporate level, financial fraud costs a cooperative society more than 680 billion dollars annually (Wells 2007). However, the costs of defection are not solely financial. Individuals suffer severe psychological consequences as a result of being victims of fraud or financial misbehavior. Such consequences include (but are not limited to) increased anxiety, depression, and even suicide (Titus and Gover 2001).

In humans, examples of deceptive strategies can take either long- or short-term forms. In the short term, individuals may execute strategies which are direct and are designed to reach broad communities, in short intervals of moderate payouts; these individuals are often referred to as con-artists or swindlers. A successful confidence artist or “con-artist” may prey on a wide variety of victims (e.g., elderly women, college students). One example comes from Pratkanis and Shadel (2005, pg. 35) where an individual would call and ask elderly individuals to donate money to a fictitious “Say No to Drugs Program.” He used very broad and flexible persuasion techniques and was

successful in getting a wide variety of individuals to “donate” to his organization. One particularly clever swindle occurred when this con-artist was arrested. Using his phone call from the Federal Marshal’s office (where he was being held), he called one of his previous victims claiming that he was a Federal Marshal and that he could recover all of the victim’s losses for a processing fee of \$20,000 (Pratkanis and Shadel 2005; pg. 42).

In contrast, some individuals execute strategies designed to reach very specific communities for long-term intervals of large payouts. These individuals are often guilty of antitrust or business/trade violations (Benson and Simpson 2009). One successful long-term cheater of this type is Bernie Madoff. Most evidence indicates that Madoff first began his fraudulent trading back in the early 1970s and eventually was responsible for the largest documented Ponzi scheme in history (Arvedlund 2009). Ponzi schemes are difficult to perpetuate because one must have great patience and build a reputation within the financial community over a significant period of time. Even more difficult, one must show initial returns in order to gain more clients to participate in the Ponzi scheme.

Although Madoff’s primary charge was running a Ponzi scheme, he used what is known as “affinity fraud” to perpetuate his fraudulent trades (e.g., Babiak and Hare 2006; Perri and Brody 2011). Affinity fraud occurs when an individual integrates her-/himself into a community for the purposes of eliciting trust and then proceeds to defraud that community. Madoff, however, went far beyond general integration into financial communities, serving on many financial advisory boards and forming long-standing relationships with important people in governmental positions (Collins 2011). Operating for almost 40 years, Madoff was able to defraud investors in excess of 65 billion dollars (Arvedlund 2009).

Although both successful con-artists and white-collar offenders (such as Madoff) have cheated innocent people out of money, they presented themselves differently. A con-artist, on the one hand, can be considered an intentional and direct defector. Con-artists and short-term deceivers use only temporary and superficial

deceptive techniques, techniques of which people are immediately suspicious (Pratkanis and Shadel 2005). On the other hand, Madoff worked himself into the fabric of the financial community through more complex deception, giving every appearance of cooperation and contribution. In essence, he imitated or “mimicked” cooperative behavior in every facet of his public life.

A comparison of human and nonhuman animal deception was proposed by Mitchell (1986, as cited in Mitchell 1996). Mitchell (1993, as cited in Mitchell 1996) argued that researchers could learn a lot about human deception by studying deception within different kingdoms of living creatures. In particular, Mitchell (1996) walks the reader through levels of deception starting with simple camouflage or mimicry all the way up to memory and perspective taking. Indeed, these more sophisticated deceptions generally require more planning and cognitive ability.

Mitchell further (1996) articulates the process of deception insofar as one must convince a target of fictional information without raising issues of suspicion. Suspicion, according to Mitchell, is the enemy of deception. This assertion makes sense, given that the human default in most cases is to believe others (Levine 2014). In fact, Levine argues that deception sometimes requires self-deception on the part of the deceived. This finding of course raises the issue of motivation. Individuals are most vulnerable to lies when they want to believe them in the first place. Take for example, someone who is uneasy about their savings with respect to retirement. This individual meets Madoff and is motivated to believe that the solution to their financial woes may be the impressive payouts that Madoff offers. Rather than raising red flags about unrealistic returns, the individual is motivated to believe that they are simply lucky to have found such a wise financial genius.

Differential Temporal Strategies

Jones (2014) argued that all deception falls on a long- to short-term continuum, and there are four key components that exist for long-term deception: complex deception, slow resource

extraction, community integration, and difficulty in detection. These four components are absent in short-term deceptions. Empirical evidence supports the idea that these four components do indeed intercorrelate (Jones and de Roos *in press*). Below we review further evidence for these claims.

Among predators and prey in the animal kingdom, mimicry is an adaptation utilized to confuse other organisms to an adaptive end (Wickler 1968, as cited in Jones 2014). In fact, many kingdoms, viruses/bacteria, plants, nonhuman animals, and humans (both children and adults), are replete with examples of some form of mimicry (Damian 1964 & Gilpin 1975, as cited in Jones 2014). Mimicry is especially prevalent when deception is adaptive for the organism (Gilpin 1975, as cited in Jones 2014).

Much in the same way that Madoff displayed characteristics of a cooperator, when in fact, he was a cheater, some animals will display characteristics that appear similar to other organisms but are actually quite different. In contrast, con-artists engage in direct parasitic and/or predatory behaviors, behaviors that are analogous to traditional infections (Damian 1964 as cited in Jones 2014) or predators (Gilpin 1975, as cited in Jones 2014).

Strategies of fraud resemble viral and bacterial infections of cooperative hosts, and as such, virulence provides a useful analogy for fraudulent behavior. Virulence refers to the rate of infection of a microorganism. Some infections spread quickly in a broad fashion, while others tailor their infection to a specific host, making the spread of infection slower, but the virus more difficult to detect (Levin and Bull 1994). Virulence, however, comes at a cost: widespread detection and destruction by antigenic entities within the host (Levin and Bull 1994). On one end of the virulence spectrum, certain microorganisms will infect a broad range of hosts. Examples of such microorganisms are *Streptococcus pneumonia* and *Haemophilus influenza*. Such microorganisms are transmitted via droplet infection (e.g., sneezing). The mechanism for infection, among these parasites, is similar in most hosts, and these microorganisms infect similar

locations within the host (e.g., nasopharyngeal passages or respiratory systems).

By contrast, certain forms of meningitis and viral infections, such as the human immunodeficiency virus (HIV), have a different approach to infection. Such infecting agents evolve within the host, in order to mimic naturally occurring cells and entities. HIV, for example, is not easily transmitted (i.e., not through droplet) and will often lie undetected for years within a host, before causing damage. These differential parasitic strategies can be viewed as two separate “defection” strategies utilized by microorganisms in compromising a “cooperative” host (Zimmer 2000). Thus, it appears in the evolutionary arms race between infecting microorganisms and multicellular hosts that many parasitic organisms have utilized mimicry strategies to appear similar to naturally occurring substances within the host’s system (Damian 1964, as cited in Jones 2014).

Mimicry also occurs in the animal kingdom when an animal or species gives the appearance of possessing characteristics of an unrelated animal or species, but actually does not possess these traits (Holling 1965, as cited in Jones 2014). Common examples can be found in organisms such as butterflies, frogs, fish, and lizards. Mimicry, which evolved for the purpose of predator confusion and defense, is often referred to as *Batesian mimicry* (Malcolm 1990, as cited in Jones 2014). Such creatures may display bright coloring or similar markings to creatures that are unpalatable or even poisonous. However, the mimicking organism is either palatable, nontoxic, or both.

Mimicry can work in the other direction as well, in favor of a predator. Some animals appear to be harmless, when in fact they are predatory. This type of mimicry is referred to as *Mertensian mimicry* (Wickler 1968, as cited in Jones 2014). For example, the Venus flytrap, which looks quite harmless to unsuspecting insects, but is carnivorous, will strike when an insect is inside.

Mimicry represents an evolutionary arms race in its own right between organisms utilizing mimicry and organisms attempting to detect mimicry (Caley and Schluter 2003). These selective pressures and arms-race style evolutionary

mechanisms are intensified by the trade-off that exists between costs associated with missing opportunities (e.g., the chance to feed on palatable prey) vs. the costs associated with making mistakes (e.g., dying from biting into poisonous prey). In other words, the cost/benefit to trusting or avoiding mimics is often based on consequences associated with false positives or false negatives. For example, if the consequence of mistaking a palatable fish with an unpalatable fish is merely an unpleasant taste, then there will be mild selective pressure placed on predators to distinguish between the two types of fish. On the other hand, if one of the fish carried lethal poison, selective pressures placed on predators for distinguishing between the two types of fish would be intense (Caley and Schluter 2003). However, as aforementioned, motivation (and therefore, self-deception) may play a role in deception as well. Take, for example, a fish that is starving, he/she may be more likely to fall for the mimicry deception, given that the trade-off of poison vs. starving increases risk-taking behaviors.

When detecting potential mimicry or deception in humans, differential pressures also produce divergent abilities for detection. For example, when consequences are low and familiarity is sparse, humans are not much better than average at detecting deception in other humans (von Hippel and Trivers 2011). In such situations of little consequence or closeness, most individuals lack the motivation and/or ability to detect deception. This lack of motivation is analogous to the lack of selective pressure on predators that face little consequence for mistaking bad-tasting fish with palatable ones. However, when consequences are high (e.g., the individual is high in closeness or the event high in consequence), detection of deception is much improved.

Deception and Evolution

Frequency Dependent Selection

The proportion of cheaters vs. cooperators follows the basic principles of frequency-dependent selection (Pfenning et al. 2001). Frequency

dependence means that too much or too little of a particular trait will create an imbalance. This imbalance is then corrected through selective pressures. Several publications have reviewed the impact of frequency-dependent selective forces on cheater vs. cooperator strategies (Mealey 1995; Wilson et al. 1996). In particular, Mealey (1995) argued that psychopathy was likely to fit in an evolutionary model mixed of cheaters and cooperators (p. 526). Mealey (1995) also noted that other variables (e.g., competitive disadvantage) played a role in determining a player's strategy (in this case, disadvantaged individuals were more likely to cheat).

In the case of mimicry, if there ends up being an exceedingly high level of harmless (Batesian) mimics when compared to harmful (e.g., poisonous) organisms, it becomes too advantageous for predators to take a risk and attack both harmful and harmless organisms, because probability is in favor of non-poison. By contrast, if the balance of mimicry to harmful organisms is such that there is an exceedingly high percentage of harmful (e.g., poisonous) organisms, then selective pressure would favor (a) finding an alternative source of food (i.e., predators would avoid both mimics and harmful prey altogether) and (b) evolving stronger mechanisms for differentiating mimics from non-mimics (Caley and Schluter 2003). In this way, a positive imbalance of cheaters might pave the way for mimics.

Among humans, some who mimic cooperation with selfish intentions may never defect unless they feel it is "necessary". However, until necessity strikes, the most effective cheaters may maintain their cooperative veneer, and thus, a positive reputation. It should be noted that necessity may be perceived differently by different individuals.

Single vs. Dual Selective Pressures on Mimic Cheaters

Frequency dependent selections also are context specific. In areas familiar to a particular type of dangerous predator or unpalatable prey, mimicry is quite effective (Pfenning et al. 2001). In such cases, predators and prey require highly evolved mechanisms to detect differences and mimicry

will often work. In areas unfamiliar to these organisms, mimicry is unnecessary. For example, Pfenning et al. (2001) placed coral snake look-alikes in eastern regions of the United States, as well as regions of Central America. They found that snake predators in the United States would readily attack these coral snake look-alikes because they had no prior exposure to such snakes or to their mimics. By contrast, coral snake look-alikes placed in regions of Central America were left alone.

By analogy, detection of deception in humans may operate in a similar fashion. For example, individuals planning affinity fraud are more likely to go undetected in certain environments once introduced (e.g., religious communities) as compared to other environments (e.g., Wall Street). Communities used to dealing in fast-paced monetary exchanges (e.g., Wall Street) are more likely to be flooded with deceptive attempts. Thus, within these communities, there is likely to be greater selective pressure placed on deceptive individuals to emulate both being a cooperator and simultaneously avoid looking like a cheater. Less pressure may be placed on someone in a community where deception is not expected (e.g., religious community).

Differentiating Human Deception Strategies

Indeed, research and theory in evolutionary models of cooperation have alluded to several permutations of cooperation that might differentially benefit the individual at the (slight) cost to the group. For example, Trivers (1971) noted that appearing to be a good cooperator with mild levels of selfish bias provides long-term benefits of resource allocation without incurring direct cheating costs. However, it should be noted that such strategies require social dominance to execute. When caught taking slightly more than one is supposed to take, it would require either refined social skills, status, or intimidation (Tooby and Cosmides 1990) to avoid having group members act in punitive ways based on unfairness.

Moreover, as Axelrod (1984) points out, strategies are contextually based, and one might cheat when costs are low, others are submissive, detection is unlikely, payoffs are great, or one feels cheated in their own right. As aforementioned, frequency dependence and the presence of others' strategies greatly influence the strategy employed by a given group member (Tooby and Cosmides 1990).

However, there is a second way an individual may engage in deception is through self-deception. For example, von Hippel and Trivers (2011) reviewed a body of evidence suggesting self-deceptive enhancement bestows advantages with respect to interpersonal deception. They argue that through deceiving oneself, detection of deception by others is rendered extraordinarily difficult. The absence of truthful leaks and/or hints of deception stem from the fact that self-deceptive individuals genuinely believe that they are cooperators, they benefit others, and they are not cheating. In sum, mimicry may be split into two forms: mimicry stemming from intentional and planful strategy vs. mimicry stemming from self-deception and exaggerated overconfidence.

Self-deceptive enhancement is a fairly broad strategy that can be beneficial (at least in the short-term). It should be noted, however, that exaggerations come at a cost. At best, these self-deceptive exaggerations represent a "mixed blessing" (Paulhus 1998, as cited in Paulhus et al. 2003), because they wear off over time.

Personality and Deception: The Dark Triad

The dark triad is a term that refers to three commonly studied personality traits in the realm of interpersonal harm (Paulhus and Williams 2002). All three of these traits are linked to deception under different circumstances (Jones and Paulhus 2016). Machiavellianism is associated with strategic and planful deception (Jones and Paulhus 2009). Such individuals are cautious and anticipate future moves from others (Bereczkei et al. 2013). In contrast, psychopathy is purely short term and aggressive in their deception,

wearing a temporary mask of deception (Book et al. 2015). Finally, narcissistic individuals deceive through self-deception (Paulhus et al. 2003). In this way, the dark triad traits cover a wide array of deceptive dispositions.

It should be noted that all deception requires some level of skill. Individuals who are convincing "talkers" often rise in corporate ranks with little substance (Babiak and Hare 2006). Skill is likely to be even more necessary for deceptions that are long term or planned. Turner and Martinez (1977) found that individuals high in Machiavellianism but low in intelligence were the least successful individuals. In contrast, those high in Machiavellianism and high in intelligence were the most successful.

Conclusion

Deceptions can take predatory and defensive forms. Further, deception ranges from simple (e.g., camouflage) to complicated (e.g., planned). In many ways, mimicry can be split into more nuanced categories, which suggests that there may be multiple forms of mimicry operating in humans as well as nonhuman animals. Moreover, there is a wide variety of deceptive tactics. Some are likely to be perpetuated by planful mimic cheaters, such as intentional information omission (DeScioli et al. 2011). By contrast, other tactics are simple and direct lies based on emotional manipulation or fabrication (Patrick and Zempolich 1999). Still others involve overconfidence and entitlement (Campbell et al. 2004). Simply put, understanding human deception is complicated because there are infinite ways to deceive, but few ways (perhaps even, just one) to tell the truth.

Definition

The progressive adaptation of human species within organized social norms that are characterized by values and social order.

Introduction

The values that describe human societies managed to create a culture that renders humans as the only species to be separated qualitatively from other animals. It is argued that the tendency of

early humans to be curious in their nature fostered the learning of useful strategies that selectively became genetic capabilities and which rendered the ongoing development of culture as a remarkable achievement. Human species evolved over generations, and communication became more complex. Arbitrary cultural meanings are found to be assigned to animate and inanimate objects in the environment, allowing for a vivid indication that early culture initiations were occurring. As communication is a vital component in the realm of enculturation, language appeared to develop in parallel with human cultural values. Throughout a continuous, systematic progress, there is evidence of memory expansion and brain size increase that facilitated and possibly co-interacted with the development of enculturation and the entry of humans in social norms.

Evolutionary Adaptability

Adaptability is of central importance to the evolutionary process. It is through adaptation that organisms are able to survive in changing environments, become better suited to their existing environment, or expand into new environments. Interpretively, organisms that are more adaptable can be expected to be more successful in evolutionary terms; a major improvement in adaptive ability is a major evolutionary advance. It is important to underline that genetic evolution has developed the superior adaptive mechanisms that have the potential to replace it in humans (Stewart 2001). The adaptive arrangements that operate within organisms during their life were discovered and established by genetic evolution. The first adaptive mechanisms established by genetic evolution searched for better adaptation by trying out changes within the organism using trial and error. As it has been mentioned above, the acquisition of language was a critically important step forward in human ability to construct mental models. Language and associated forms of communication enabled humans to share the knowledge used for building models (Popper 1972). Communication enabled all members of a society to acquire and use the knowledge discovered by any individual.

It also enabled knowledge to be accumulated across generations. The progressive accumulation of knowledge allowed the individual to model greater range of interactions with the environment and to predict the consequences of their actions (Stewart 2001). Consequently, this notion encouraged human species to discover effective ways of achieving adaptive goals and obtaining positive reinforcement from internal reward systems. Nevertheless, human species have a very large evolutionary blind spot. Humans are not motivated to explore an immense variety of adaptive possibilities, regardless of how useful they may be in evolutionary terms. Until this limitation is eliminated, continuous use of genetic engineering, artificial intelligence, and other technological advances will be needed to satisfy past evolutionary needs and conditioning, rather than to achieve future evolutionary success.

Social Values

Societies seek to establish congruence between social values associated with their activities and the norms of acceptable behavior in a larger social system (Weigert 1983). Values foster harmony within a human society and function as the foundation of organizational legitimacy. The absence or violation of cultural common values leads to disparity that can threaten congruence and undermine unity within a society (Cooley 1953).

Emergence of Identity within Culture

In developing their sense of identity, people identify successively with values of influence over their well-being. The primary processes involved in identity development are ones of enculturation of cultural elements (Berry 1980). Enculturation references the agentic individual's process of identification with whatever cultural elements of influential others are accessible to the person (Weinreich 1983). In the main, the young child identifies with mother and father in the first instance but identifying only with limited aspects of them apprehended from the child's perspective. Subsequently, the person as older child, adolescent, and then young adult successively identifies

with members within their direct environment, and beyond with agents of the wider community, and part-identifies with their salient features according to increasing levels of comprehension (Erikson 1950, 1968). As a consequence, over a formative period, the child who becomes the adult migrant will have enculturated major aspects of heritage culture including some elements that are incompatible with others, since cultures are not entirely monolithic (Liebkind 1989). According to ISA, identity is a modification of earlier ones and emphasizes people's construal of their biographical past and their aspirations for the future. For human species, their biographical past scenarios can be located in their heritage locations and cultures, while their future aspirations may entail considerations about their intended modes of engaging with their receiving communities (Weinreich 2003).

Morality

Contrary to the belief that wants morality to encompass a trait unique to humans, it is argued that other animal species may possess moral behaviors including community concern, reciprocity, and empathy. Although it is not supported that a fully developed moral system is present in other animals, it is indicated that human morality is embedded in phylogenetic relationships with ancestral animal species. Evolutionary scientists depict the phenomenon of homology by rendering the presence of shared behaviors as the result of a common ancestor between humans and other animal species. They also support that two distantly related species can share a behavior while they inhabit similar environmental niches as it results from convergence due to shared environmental constraints. Intriguingly, examining behavioral patterns of other species might explain mechanisms of human behavior and depict that a multitude of phenomena concerning morality are the result of continual evolution (Dennett 1995).

Darwinism and Moral Emotions

Charles Darwin proposed that the basis of morality is innate and that humans and animals share an

evolutionary background. He mentions in his book *The Descent of Man and Selection in Relation to Sex* that nonhuman primates possess social instincts, such as parental affection, and they are consequently characterized by a sense of conscience that would be otherwise intellectual power if it was well developed as it is in humans. It is argued that other animals experience some level of sympathy for others in their environment that also includes a strong need for familial interactions (Darwin 1964).

Darwin does not disregard the importance of advanced intellectual ability for meaningful judgment, but he underlines that well-marked social instincts are present in animals indicating moral constraints and conscience in species other than humans (Darwin 1981). He supports that this notion functions as an evidence for evolutionary continuity between humans and other animals as he relied on comparative data regarding facial expressions across human cultures and other species. He addressed the reasons why universal behaviors are expressed in the form that they do (Darwin 1998).

Adam Smith appears to support Darwinian theory. In his book *The Theory of Moral Sentiments* discusses that both positive and negative passions are seen in animals and that they share many traits that are considered human. To support his views, Smith mentions that all animals, including children and dogs, are likely to become angry at inanimate objects that hurt. He highlights that human instincts were in place to promote survival and reproduction. He further believed that instincts were initially experienced as emotion, rather than rational thought, and were often laid outside conscious awareness (Smith 1817). The idea of evolutionary continuity of behavior and the recognition of moral emotions has its roots embedded in the ancient past.

The Empirical and Normative Senses of Morality

Morality from a scientific perspective refers to a set of empirical phenomena, such as the observed capacity of human beings to make normative judgments and the tendency to have certain sentiments including sympathy, guilt, or blame as well

as intuitions about fairness and violence. Scientists speak of the evolution of morality in empirical sense while utilizing tools as comparative genomics and primate studies to analyze the subject of interest. While morality in the normative sense is not an empirical phenomenon to be explained, there are vital points that require attention regarding evolutionary theory and principles (Rosenberg 2006).

The normative sense of morality questions one's evolutionary background for moral guidance; through the normative approach, scientists might attempt to gain insight into the content of morality as claimed by proponents of prescriptive evolutionary ethics. Evolutionary theory can potentially explain metaethics and allow to resolve inquiries about the existence and nature of morality (Biniolo and de Anna 2006). Once topics of interest are selected, scientists begin to consider scientific explanatory projects concerning morality in the empirical sense.

Moral Behaviors in Nonhuman Species

Moral emotions have been identified as the principle mechanisms that uphold the rules of behavior underlying social norms and conventions (Mead 1934). They constitute vital components in interactions as they normalize the behaviors of group members and foster the tendency to be in line with the norms (Haidt 2003). Equity and equality are the two primary elements that synthesize justice. Adam Smith refers to justice as “the main pillar that upholds the whole edifice of human society.” This perspective lies within the rationale that wants animal species to react in the face of unfair treatment. This notion argues that based on instincts of moral behavior, primates tend to respond negatively when others are treated less well, a fact that contributes to the maintenance of harmonious coexistence among group members (Brosnan 2006).

Studies on Moral Behavior in Primates

Naturalistic studies have shown that long-term behavior of the partner is more important than the outcome of the individual. In an experimental cooperation task, subjects were more likely to cooperate if they and their partner evenly shared

the rewards. In one study, monkeys had to work together to pull a heavy tray of food. The foods differed every time, and the monkeys had to decide whether they were willing to work for the food reward they were offered. Pairs in which the partners shared the good food about half of the time were successful in the cooperative task, while pairs in which one partner eliminated the other rarely obtained cooperation. Aside from the fact that non-sharing dominants received higher value rewards than their partners, their success rate was lower; thus, they tended to receive fewer rewards. The subjects seemed to expect that working together on a task leads to equity if reward outcome and dominant partners who failed to do this received a form of punishment (Brosnan et al. 2006). The findings indicate that a critical factor in a cooperative task is the partner's behavior to be equitable, rather than the actual value of reward. In experiments where participants are humans, responses to inequity differ depending on the source (Silk et al. 2005). Humans change their responses if there is a reason for inequity (Tajfel 1981). Individuals offer less, and partners accept inequity more readily if the subject is perceived to have earned the right to it. Interestingly, humans tend to respond more negatively to inequity that is caused by another human directly than to inequity that is the result of chance.

Evolution of Justice

The sense of justice is seen in nonhuman primates as they are likely to respond negatively to earning less preferred rewards than a social partner. In respect to natural selection, researchers argue that it might have been a critical environmental factor that led to selection for the behavior (Darwin 1964). It is important to underline that evolution of shared behaviors does not indicate identical approaches from species as well as it does not eliminate the novelty of behaviors that are unique to specific primates, but not others, due to their complex nature. Nonetheless, inequity can be explained as the byproduct of another behavior that led individuals to selectively focus on

conspecifics, such as social learning, which is present in many species and can be beneficial (Kelly 1955). On the other end of the spectrum, inequity superficially might not be perceived as rewarding from species due to unjust circumstances; however, reacting negatively to unfair treatment can cease harmful interactions with opponents and encourage them to seek out equitable partners (Brosnan 2006). There is also evidence that human and nonhuman species actively take steps toward rectifying inequity when the moral sense of justice is violated, and they receive less than they deserve (Brosnan 2008). In this stage, primates react by punishing others who do not play fairly (Fehr and Gächter 2002). It can be argued that reaction to disadvantageous inequity is more salient as there is immediate benefit to the partner. On the other hand, advantageous inequity leads individuals to abandon their own good and act against their short-term self-interest in order to give up rewards to benefit others. The definition in itself might seemingly appear disastrous for the individual; however, it derives long-term benefits for the community and the conservation of healthy social norms.

Embodiment of the Self in the Community

Rites of Passage

A rite of passage is a ceremony and marks the transition from one phase of life to another. It plays a critical role in the evolution of human civilization as it defines the common values of a society. A rite of passage manages to conserve social order and the sense of community among the members of a group who come together to celebrate an occasion and practice traditions and customs on the foundation of shared social values. Rites of passage are characterized by the ordeals with which a youth is formally invested with adult status in a community. Intriguingly, these rituals and ceremonies allow adults to transition into new life roles along the path of adulthood, all the way into meaningful elderhood. When humans design rite of passage experiences, they work to assure

that initiates come out of the experience with a new and empowering story that helps them take responsibility for the decisions that set the course of their future. Members of a social group initiates create the story of who they are and the kind of life they wish to build based within the exploration of their own personal values. Initiates are encouraged to select the story that connects them to their community. Through this self-exploration, they emerge with a stronger sense of personal responsibility to all aspects of their lives, stretching all the way out to the larger world of which they are a part of (Carrithers et al. 1985). Consequently, both the community and the initiate benefit from a rite of passage. An intentional rite of passage experience provides the space for the community to transmit its core values and ethics and confer the role responsibilities appropriate to the initiate's stage of life, hence insuring cultural continuity and knitting together of the generations.

The Role of Honor Code

A fundamental aspect of culture is its embodiment of the societal processes of substantial groups of people who perceive themselves as belonging to a commonality of values and beliefs, moral imperatives and religious beliefs, dress and behavior, history, and modes of living, whereby one group is culturally distinctive from another (Henry 2008). From evolutionary perspective, honor codes appear to maintain cohesive order within communities. The role of an honor code is to encompass a set of ideals in a society and govern accordingly a group of individuals that abide by moral rules. It is based on what constitutes honorable behavior among group members, and its use depends on the notion that individuals within the group can be trusted to act honorably. In many cultures, an honor code exists parallelly to ethics that require proper compliance according to societal rules, by members who seek to be recognized for their individuality and be inviolably included in community. Punishments upon disregard of the honor code underline that values-driven individuals ought to be more successful within a society.

Development Levels for Compliance and Ethics

From evolutionary perspective, crucial components that characterize honor codes of human societies appear to be diachronic as they influence critically the man of today who seems to adhere to values that had always fostered healthy functions in communities since ancient times. Modern society has adopted these values and incorporated them into organizational honor codes. Foundation-level programs set the basis for establishing a healthy organizational culture and preventing, detecting, and resolving legal and regulatory compliance violations. The behavioral focus is on compliance, and the business focus is on the organization. Transformation-level programs support a shift from a compliance focus to a compliance and ethics focus. The behavioral focus is on compliance and ethics promoted by values-based leadership. The business focus is on the organization and primary stakeholders which might be customers, suppliers, investors, financiers, and communities in operating area. Sustainability-level programs foster aspirational behavior and contribute to the organization's continued success. The behavioral focus for this level is on compliance, ethics and honor, collaboration, and meaning, all promoted by values based on leadership (Keegan 1994). Hence, the business focus is on the organization, primary stakeholders, and secondary stakeholders which might be special interest groups, media, government, competitors, consumer advocates, and global society (Henry 2008).

Spiritual Development

Humans have assembled a remarkable body of knowledge about how they can develop new psychological capacities. Such knowledge is embodied in religious and spiritual systems. Even though systems differ in the expression of their goals, the world's major religious systems advocate the cultivation of the human ability to free oneself from particular emotional responses, desires, and motivations. All systems contain methodologies that

aim to assist the development of such capacity. Religious systems generally promote the emergence of the new self through practices that separate the mind into an observing part and an observed part (Nicol 1980). The observing part is the precursor to the new self. These practices typically operate by turning attention and awareness inward and directing it at mental contents such as sensations, emotions, motivations, mental images, and thoughts as they arise in the mind (Goleman 1988). For instance, many religious systems require adherents to struggle against the dictates of their lower desires and impulses facilitating significantly the process of human enculturation. Doing so renders these mental states objects of attention and begins the separation of the mind into an observing part and an observed part.

The Role of Spiritual Meditation in Enculturation

Intriguingly, the concept of culture is not only characterized by participation of the individual in community but also by the separation from the massive group in an attempt to grow intellectually, enrich their mental capacities, and acquire identity for the inner and outer self. Meditation involves turning attention inward and making thoughts as emotional states objects of attention. Mindfulness practices and self-observation promote the development of the new observing self during ordinary life. These practices focus attention on the physical sensations, emotions, mental images, and thought that arise as the individual goes about daily activities and interactions; these techniques emphasize that self-observation is to be passive and non-judgmental (Nicol 1980). Evolutionary scientists argue that mental capacities of this kind characterize the primitive man and his spiritual practices back in the old antiquity. They have always allowed the individual to accumulate knowledge about the operation of their motivational and emotional system and improve their capacity to manage them. The result is a new emerging self that can remain functionally separate from motivations and emotional impulses and can decide whether or not to be influenced

by them. This separation enables the new self to control the disposition of attention. The individual can direct their attention and energy at activities that serve the aims of the self. As a result, he/she can be motivated and emotionally satisfied in the activities that serve their goals. If an individual decides to pursue evolutionary success as their ultimate objective, they will be able to align their internal reward system with evolutionary goals (Stewart 2001).

Conclusion

Enculturation of elements represented by moral and social values is a process of incorporation of cultural elements to become elemental aspects of one's overall identity. The continuous process of human enculturation is the foundation of the person's identification as well as the coexistence of mixed cultural elements within the person's identity. Ultimately, the goal is the creation of elemental identification that is characterized by common values and is expressed within social boundaries, honor codes, and moral incentives. A better understanding of the evolution of moral behaviors can be achieved through examining outcome behaviors that allow for insight in the past. According to the notion of natural selection, salient behaviors were practiced more than others, rendering certain moral tendencies as vital for survival. Values of justice and equity appear to be among some of the most crucial components to maintain social norms and community order intact in communities of human and nonhuman animals. Undoubtedly, intellectual ability and moral judgment of humans are not comparable with those of other species; nevertheless, the presence of social instincts functions as an evidence of moral conscience in other species. With respect to moral behaviors and emotions, through approaching the precursors, such as the inequity response, scientists may gain a better insight into the outcomes of evolution of moral behavior. Since clear continuity has been determined between the species, it can function as the foundation of future research on evolutionary approaches to human morality.

Human Genome Project, The

Definition

The Human Genome Project was an international research project that mapped and stored all 3.2 billion base pairs in the human genome.

Introduction

The Human Genome Project (HGP), successfully completed in 2003, was an international collaboration that accurately sequenced and mapped the entire euchromatic portion of the human genome. Two separate drafts of the human genome DNA sequences were published in 2001 as a consequence of the race between Celera Genomic's privately funded and the International Human Genome Sequencing Consortium's publicly funded initiatives. Their goals were to sequence all the nucleotides of the human genome, create databases to store this information, and develop tools to analyze this massive amount of information. Completing the project required collaborators from the UK, France, Japan, Italy, Canada, and Germany and costs approximately \$3 billion (International Human Genome Sequencing Consortium 2004).

History and Significance

In 1986, over 30 years after James Watson and Francis Crick first discovered the structure of DNA, Italian Nobel laureate Renato Dulbecco supported the creation of a project aimed at

sequencing the complete genome of an organism. While he was not the first to propose such an undertaking, his commentary in *Science* propelled the concept of a HGP into scientific mainstream. Its independent origins stem from Dulbecco, Robert Sinsheimer of UC Santa Cruz, and the Department of Energy's (DOE) Charles DeLisi (Berg 2006). Though each with his own specific reasons, ranging from understanding cancer to detecting chemically induced mutations, they understood that this colossal feat was needed to completely understand the genetic basis of human illnesses and diseases. The project was officially launched in 1998 by the DOE and the National Institutes of Health.

Before the HGP, stretches of genetic material had only been examined through individual small-scale experiments. DNA is the code that makes thousands of genes that keep a cell living. This code is made of four chemical bases, called nucleotides, ordered along a sugar-phosphate backbone of the DNA double helix. An organism's genome is the entire DNA sequence of one set of chromosomes. Humans have 23 pairs of autosomal chromosomes, which are identical in males and females, and a set of sex chromosomes, which are different between males and females. Each chromosome consists of around 50–300 million nucleotides, but because of DNA's double helix complementarity, the makeup of one strand provides exact information about the other strand. The complete human genome consists of 3.2 billion nucleotides, however knowing just the arrangement of the bases (called a sequence) does not give any information of where the genes are located on the chromosome (called a map), the function of each genes, or what genes correspond to which proteins. The difficulty of the HGP was to both sequence and map every single nucleotide (International Human Genome Sequencing Consortium 2001).

The laboratory techniques in the 1990s were not able to yet read the three billion sequence from end to end. Sequencing at this scale was a laborious process as the HGP Consortium started by using clone-by-clone sequencing to create a crude physical map of the genome before sequencing the DNA. In this method, long strands

of DNA are cut into smaller 150K base pair long pieces and then into a bacterial artificial chromosome (BAC) vector, an artificial chromosome from a bacteria. A BAC is a piece of circular DNA that can reproduce inside a bacterial cell, so each time the bacteria divides, the inserted human DNA is copied. All of this DNA is broken down into small overlapping pieces, sequenced, and then pieced back together using areas of overlap to reform the large original pieces originally inserted into the BAC (International Human Genome Sequencing Consortium 2004). While each piece is from a known region of the chromosome, making clones and creating genome maps is expensive and time-consuming. Furthermore, this type of sequencing cannot be used on centromeres or telomeres, the tightly packed middle and ends of a chromosome, because they contain long repetitive sequences (Venter et al. 2001).

Craig Venture and his company Celera instead pushed forth a method that bypassed the step of using BAC clones entirely. In this method called shotgun sequencing, the whole genome is broken down into small pieces that are easy to sequence. Then, using massive computing power, the pieces are assembled by a computer program that looks for small overlaps between the pieces (Venter et al. 2001). Because this eliminates the physical mapping stages needed for BAC clones, sequencing is faster and less expensive.

The HGP used genetic material from five anonymous donors in order to create the reference map we have today. Scientists collected blood and sperm samples from individuals of European, African, American, and Asian ancestry, so the completed genome was a composite of DNA and not a specific individual's genetic information, called a reference genome. A major finding of the HGP was that all humans contain the same large set of genes and genomic regulatory regions that direct development (International Human Genome Sequencing Consortium 2004). People only deviate in 1 out of 1000 bases, so this reference genome is 99.9% identical across all humans, regardless of race (Venter et al. 2001). While each person's genome does contain individual variations, the conclusion of the project dismissed many genetically based ethnic differences.

Scientists were also surprised to discover that humans only contain 20,000 genes, a number far lower to pre-HGP predictions of 100,000 genes (International Human Genome Sequencing Consortium 2004). As humans are arguably the most complex organisms on earth, researchers assumed that we would contain the largest number of genes. While 20,000 is more than a rodent, it is not much larger than other apes. Even more astonishing was the discovery that genes only make up 1% of the genome. The rest, once considered junk DNA, is vital in regulation when and where genes are turned on and off.

The project had an immense impact on all of science, chiefly because it accelerated the advancement of DNA sequencing technologies. The first genome took around 13 years to complete, but since then scientists have been able to sequence the genomes of other organisms within a year. The price to sequence an entire human genome now only costs around \$1000 which allows for detailed comparisons across thousands of individuals. Moreover, since the completion of the HGP scientists have identified the genetic basis of more diseases, like autoimmune disorders and specific types of blindness. Research studies have also linked over 200 genes to types of cancers – triple the number that was known before the HGP. The completion of the project has heralded in a new age of personalized medicine and revolutionized genomic technology.

Conclusion

The HGP was an international collaborative project that identified and mapped the 3.2 billion base pairs that make up the human genome. Initiated in 1990, the project took 13 years to complete and led to many significant advances in sequencing technology. Using wholegenome random shotgun method and hierarchical shotgun methods, the collaboration built a genetic and physical map of the genome. Most striking, researchers discovered that the genome only contains around 20,000 genes and 99.9% of nucleotides are identical between any two people.

Definition

Aggregates of individuals united by specific relations or characteristics, which make them distinct from other aggregates.

Introduction

Social life in human societies relies on interactions and cooperation between their members. At the same time, the distribution of these interactions is not equal across the whole population. Instead, social life goes on within collectives, or groups, uniting a number of individuals. Such collectives are distinct from other collectives and exist in many different forms, from small family groups to states and nations. Although it might seem intuitively clear what a “group” is, its scientific description turns out to be very difficult. There are two general approaches to understand the nature of human groups. The first one is based

on researchers’ goals and interests, whereas the second one is based on lay people’s perception of groups.

Social Group as a Researcher’s Construct

The first approach to understand human groups is more analytical and based on researchers’ decisions on what constitutes a group and how can it be identified. Depending on research goals, many alternative criteria for group identification can be proposed. For example, an evolutionary biologist can make this decision on the basis of genetic similarity, an anthropologist can rely on spatial characteristics of residence, a sociologist can group people according to the statistical analysis of survey results, a psychologist may focus on self-identification with a group, a social network analyst will probably look at the density of electronic connections between users. The multitude of the possible criteria underlying group identification and multitude of groups in which humans can be included is a challenge for any science treating groups as separate units of analysis and especially for any science treating them as real entities.

Such difficulties are evident in evolutionary biology and, particularly, in group selection approach because of the necessity to determine to what types of social collectives any group-level evolutionary mechanism should be applied. When evolutionary arguments are applied to human groups, they are typically refer to those ones, which are common in primitive societies and more resembling animal groups. The two most important forms of social organizations in such societies are families and local groups. Whereas the former are directly involved in daily routines, child-rearing, and mutual aid, the latter are based on a more large-scale cooperation necessary for complex tasks, wars, or rituals necessary for maintaining group solidarity (Johnson and Earle 2000).

Such groups are considered by some evolutionary biologists as examples of “adaptive units” which are the object of natural selection as well as individuals (Wilson 2006). According to this multilevel selection approach, group-favoring

behavior should be understood in terms of individual's absolute fitness rather than relative fitness within a group. At the same time, direct application of the kin selection theory to larger ethnicity groups faces difficulties due to enormous complexity of larger groups' social and normative organization (Jones 2018). Within large social groups, psychological processes necessary to cooperate and regulate social relations become extremely important. The multilevel selection theory argues that such psychological processes (e.g., underlying collective decision-making, imitation, or social control) can still be understood as group-level adaptations, because they make possible the existence of specific types of groups (Wilson 2006).

The argument of the multilevel selection theory that groups are adaptive units in the same sense as individuals raises another question: Are they real? Or, to be more exact, Should human groups be treated as entities? This question, albeit in a varying forms, underlies long-lasting discussions in sociology and other social sciences often treating collective forms of social life such as corporations, states, or institutions as social entities within "social reality". However, both in evolutionary and social psychology, such views are seldom. Within these disciplines, psychological processes and behaviors are attributed to individuals even if collective phenomena are under consideration. Any group-level effects are seen as resulting from interaction and communication between individuals. Unlike individuals, groups are unobservable as entities, have no clear boundaries comparable to those of an individual, and cannot perceive, feel, think, or behave in the strict sense, i.e., irrespective of individuals' cognitions and behaviors.

Another difficulty is the great amount of group types in which humans exist. In modern societies, individuals participate in numerous collectives which can be called groups: families, local communities, organizations, nations, ethnic groups, religious groups, political parties, customers, sports fans, etc. Treating each of them as a real entity is theoretically challenging.

To overcome these difficulties, an American psychologist Donald Campbell introduced the

notion of group's *entitativity*, i.e., the degree to which a particular aggregate of persons can be considered as an entity (Campbell 1958). The matter of group's reality thus becomes a matter of degree rather than yes-or-no question. Relying on psychology of visual perception, he proposed a number of principles, or criteria, which could be used to treat human groups as more or less entitative. Those are common fate, similarity, proximity (as condition of face-to-face communication), permeability, and some other. This approach is more realistic and allows thinking about human groups in terms of many specific group characteristic, although it depends a lot on the choice of measurement procedures used to describe a group.

Lay Theory of Social Groups

An alternative approach for understanding the nature of human groups refers to individuals' own perceptions of group and intuitions about what constitutes a group and how it differs from other groups. A number of studies conducted by B. Lickel, D. Hamilton, S. Sherman, and several other psychologists revealed important regularities of people's perception of social groups. They used several methods: explicit rating of 40 different groups according to their characteristics, voluntary sorting of these groups into categories, analysis of identification errors during face recognition (Lickel et al. 2000; Sherman et al. 2002). In the explicit rating task, participants rated each of the 40 groups according to their perceived entitativity and 8 properties: interaction between members, importance of a group for its members, shared goals and outcomes, similarity of group members, permeability, group size, and the duration of its existence. Analysis of participants' choices allowed to identify four different types of groups:

Intimacy groups (family, small group of friends, romantic partners, etc.) are the highest in entitativity and are characterized by high interaction and personal importance for their members, as well as common goals and outcomes.

They are small in size, have low permeability, and relatively long duration. The level of perceived similarity among their members is also the highest among the all group types.

Task groups (e.g., sports team, rock band, coworkers, etc.) are also high in perceived entitativity, small in size, moderate in permeability, have moderately high level of interaction, shared goals and outcomes, personal importance, and members' similarity.

Social categories (e.g., women, Jews, Americans, Blacks) have intermediate perceived entitativity, are very large, and have the longest duration. At the same time, they are low in members' interaction, shared goals or outcomes, as well as personal significance and similarity.

Loose associations (e.g., people at a bus stop or in line at the bank) are the lowest in their entitativity and highest in permeability. Other group's properties for loose associations are low; they exist for a short time, their members have little interactions, are not similar, and don't share goals and outcomes much. Their personal significance for the members is also the lowest among the all group types.

The analysis of the studies' findings led authors to the conclusion that in terms of subjective perception, entitativity is strongly correlated with members' interaction and similarity, shared goals and outcomes, and personal importance. Additional studies showed that when people treat the groups to which they belong, their perceived self-importance and entitativity are also strongly correlated (Lickel et al. 2000). It is also supposed that other contextual and motivational factors, such as intergroup relations or personal goals can influence perceptions of groups. Culture is another important factor, which can determine the subjective perception and meaning of groups. In particular, collectivist societies are supposed to attribute more entitativity and agency to groups than individualist societies (Tsukamoto et al. 2018).

Subjective perceptions of groups and their properties are psychologically meaningful and

related to many aspects of human cognition and behavior. They are used to explain and predict the social world, necessary to choose appropriate strategy. Defining group boundaries and perceiving their entitativity and other attributes is a necessary prerequisite of most effects associated with group membership: social identity, intergroup biases and prejudices, in-group favoritism, intergroup relations, perception and regulation of social relations (e.g., Lickel et al. 2001; Effron and Knowles 2015).

The four types of groups listed above are identified in various studies using different samples and methods. Recent studies show that the differences among these group types appear in childhood, so that 5–6 years old children differentiate between them and ascribe some degree of entitativity to all of them except for loose associations (Plötner et al. 2016). This allows to suppose that the lay theory of groups is a part of those universal psychological processes which, according to the evolutionary approach, underlie human ability to compose groups which can be considered as real social unities (Wilson 2006). Thus the two approaches described above are not necessarily contradicting each other.

Conclusion

Groups are the key element of the social organization of human societies studied by various social disciplines. The main difficulty of studying human groups is their enormous diversity and the fact that individuals belongs to a great amount of them, contextually change their memberships and relations to other groups. For psychological science, identification of group types is crucial as it helps to systematize behavioral and relational patterns of social life. The idea that humans organize their knowledge of groups according to some common principles is crucial for understanding these regularities and bridges the gap between evolutionary notion of groups as adaptive units and psychological reality of actual group perception.

Definition

Strategies, communications, and actions that have the intention of attracting someone who is already in a romantic relationship, with the purpose of

dissolving that relationship and forming a new relationship with that person.

Introduction

A significant portion of human mating research considers male and female intrasexual competition as limited to competing for available mates in a pool, for either short-term or long-term relationships (or both). Much of this is captured well by sexual strategies theory (Buss and Schmitt 1993). However, competition can continue well into established relationships, as Schmitt and Buss (2001) demonstrate and develop in a series of studies on human mate poaching (“behavior intended to attract someone who is already in a romantic relationship,” Schmitt and Buss 2001, p. 894). This topic clearly extends human mating research to include ongoing relationship issues, including relationship maintenance and dissolution, and the fact that aspects of these issues involve others outside the actual relationship. Across most of human evolutionary history, it would have generally been advantageous to secure additional mating experiences via poaching and correspondingly detrimental to have one’s mate poached. Therefore, we can expect that modern humans also, to some degree, utilize mate poaching as a method of securing mates. This behavior, operating at both a conscious and subconscious level, can be directed at either short- or long-term contexts. Whether a brief affair or a more permanent coupling, there is some degree of premeditation involved from the mate poacher because they engage in actions meant to draw their desired partner away from the already-established relationship.

Patterns of Human Mate Poaching

Schmitt and Buss (2001) predicted that patterns would emerge that could be predicted from an evolutionary lens. For example, one method of mate poaching occurs through engaging in extra-marital affairs, which (depending on the study) occurs between 20% and 50% of the time. While

many of these affairs are short term, there is a pattern of poaching for long-term partners as well. Another example is that of serial monogamy, viewed as long-term mate poaching, which is a feature of mating in many cultures. Therefore, an argument that long-term mate poaching might be part of our evolved mating psychology is feasible. These patterns of mate poaching are extensively historically documented and have been found in literature and mythology.

Empirical Evidence for Mate Poaching

Four studies are reported in Schmitt and Buss (2001), supporting and developing the idea of human mate poaching. The first study found that substantial proportions of people had personal experiences related to mate poaching, across both undergraduates and a broader convenience sample of participants. This included experiences attempting to poach a partner from someone else and experiences with someone trying to poach them away from a committed relationship. Of the participants that reported being in a relationship, between 12% and 27% indicated that their current relationship resulted from poaching their partner away from someone else and between 20% and 41% reported that their current relationship was a result of them being poached from a previous relationship. Higher scores on the personality traits of agreeableness and conscientiousness were associated with less likelihood of poaching attempts, whereas higher scores on the traits of extraversion and openness to experiences were associated with being more likely to experience poaching attempts directed toward themselves. Personality features related to accepting poaching attempts included being disagreeable, neurotic, and unconscientious, as well as having low relationship exclusivity scores, a masculine gender orientation, and low emotional investment.

As a preliminary step for Study 2, small groups of some of the prior participants were asked to generate potential short- or long-term costs or benefits of mate poaching, for either men or women, within moderated focus groups. These

were transcribed and summarized into 73 distinct items that were themselves grouped based on conceptual similarity. Study 2 had four hypotheses:

- (a) Men should view the physical beauty of the person they were poaching as a larger benefit than the women in the sample.
- (b) Women should see potential partners with more resource control as a larger benefit than would men.
- (c) Men should perceive short-term poaching opportunities as more beneficial than women because it satisfies evolved desires for sexual access and variety.
- (d) Both men and women should view commitment threats in the long term as costlier than those that threaten short-term fidelity.

Ratings of the 73 mate poaching costs and benefits by undergraduate participants (focusing on variables of temporal context, sex of actor, and sex of rater) supported all four of the above hypotheses.

The structure was similar for Study 3, in that an initial group of participants generated 60 individual behaviors and tactics associated with mate poaching (i.e., male and female attraction methods). Separate undergraduates then rated each of these 60 tactics for effectiveness for either attracting a short-term partner or a long-term partner. The results of these ratings supported five hypotheses for Study 3:

- (a) Enhancing one's own appearance and derogating a rival's physical appearance should be less effective as an attraction technique for men than for women.
- (b) Men should have better success when drawing attention to their resources and their willingness to devote those to a potential partner.
- (c) The suggestion of low-cost sexual access should be more effective for women trying to poach a mate in the short term.
- (d) When attempting to poach a partner, men and women should experience different levels of success when they make that person question their current partner's fidelity.

- (e) There should be an interaction between sex and temporal context (i.e., poaching for a short-term or long-term relationship), such that men attempting to poach for the short term should be rated as most effective when displaying dominance over the rival mate. (This final hypothesis was qualified by the finding that dominance display, although rated as more effective for men in a short-term context, was not rated as the most effective tactic in terms of absolute ratings.)

Study 4 extended the results of Study 3 by changing the relatively vague relationship context of Study 3 (short and long term) to a broader and more specific set of relationship contexts: married, dating, living together, long distance, highly committed, not committed, just beginning, and about to end. The same five hypotheses generated for Study 3 were utilized again and were again supported by the results. Furthermore, the more diverse set of relationship contexts in Study 4 produced several more nuanced findings that go beyond those original hypotheses. For example, women's use of appearance enhancement (as a mate poaching tactic) was judged least effective when targeting married men and most effective for targeting men in noncommittal relationships. Similarly, men's use of resource control demonstrations was judged as less effective when targeting women in a very committed relationship and most effective when targeting someone just beginning their relationship.

Limitations and Impacts

Schmitt and Buss (2001) set out a theoretical and methodological framework for studying a previously unexplored area within human mating, mate poaching. Their empirical results then provided evidence of the validity and value of this topic. As the authors noted, though, some limitations existed with these studies. The Schmitt and Buss (2001) studies are almost entirely based on university undergraduates, and it would be beneficial to employ more diverse samples – particularly utilizing various age categories. Additionally,

these studies evaluated the reported perceived effectiveness of various mate poaching tactics, not the actual or absolute effectiveness of any of these tactics. Finally, it is possible that the artificiality of these study methods (i.e., text descriptions) did not capture the complexity and subtleties of mate poaching in the real world. There likely are nuances in the tactic, timing, and deployment of each of these techniques allowing them to co-occur and depend on the skill or relationship status of the individual enacting them. Addressing each of these limitations required more extensive and difficult research projects, with Schmitt and Buss (2001) serving as a foundational springboard for cross-cultural studies (Schmitt 2004), examinations of tactics poachers use (Schmitt and Shackelford 2003), and in-depth research on specific personality characteristics (for examples, see Jonason et al. 2010 or Kardum et al. 2015).

Since its publication, Schmitt and Buss (2001) have received a strong and consistent level of citation in the research literature and elsewhere. Google Scholar (<https://scholar.google.com/>) counts a total of 442 citations of Schmitt and Buss (2001) between its publication and November 2019. Furthermore, the citation rate for this publication has been increasing over time. During the 2000s, it received 10–20 cites per year, but in the 2010s it has been consistently receiving about 30 cites per year. This is a relatively unusual pattern of citations over time, indicating a seminal paper on a topic that is becoming increasingly relevant.

Conclusion

The broader discussion of human mating strategies in Schmitt and Buss (2001) opened a new vein of research in the area of mating relationships. It was the first article to systematically explore the evolutionary case of mate poaching, including questions about how frequently the tactic is employed, associated individual differences, costs and benefits for both sexes, and the relative success of different strategies. It also

provided valuable contexts for work on rival derogation and self-promotion by pointing toward powerful situations in which those phenomena would be particularly prominent. This laid a foundation for extensive research that followed.

In agreement with broader infidelity studies, mate poaching is a frequent strategy that succeeds in a larger-than-expected number of cases. This strategy is associated with several distinct individual personality characteristics (a finding further supported by Sunderani et al. 2013, in addition to those mentioned previously), and the success of this strategy is likely dependent on both the characteristics of the poacher and the poached (for another example, Parker and Burkley 2009). Similarly, there are unique costs, benefits, and response options for each party involved in a mate poaching scenario, and, given that a large portion of mates in any given mating pool are already partnered, mate poaching inherently creates adaptive problems for the person whose partner is being poached (for further research on costs and benefits, see Davies et al. 2010). Schmitt and Buss anticipated that mate poaching likely coevolved with methods for mate guarding and retention tactics. Since its publication, further findings have broadened our understanding of, among other things, how individuals cope with mate poaching (Ein-Dor et al. 2015) and its coevolution with mate guarding (Buss 2002).

Definition

Human nature refers to psychological aspects and behavioral traits that are common to most people. Biocultural evolution is the process by which biological and cultural aspects interact to shape human nature throughout human evolutionary history.

Introduction

One of the most intriguing topics of scientific investigation is human nature, why humans behave the way they do, having been the object of study of a wide variety of disciplines, including psychology. Despite the volume of research, human nature has not been completely unveiled. This is partly due to the controversy over the extent to which human behaviors are a product of their environment or of their genetics, resulting in the “nature versus nurture” debate that has been the focus of scientific discussion since classical times (Thorpe 1974). Philosophers such as Locke and Rousseau, for example, adopted the nurture side of this debate, advocating that the newborn child is a *tabula rasa*, a blank slate, and as such, the essential nature of a human being is inscribed as a result of learning and other interactions with the environment during the life course. Conversely, thinkers as Hobbes and Spencer believed that genetic makeup determines to a very large extent essential human nature. Nowadays, this

dichotomy between nature and nurture is largely deemed false with the view that an interaction between the two results in human behavior: that “every bit of the behaviour (...) of every single organism living on the face of the earth results from the interaction of genetic information stored in the developing organism and the properties of its environment” (Richerson and Boyd 2005, p. 9).

There is little doubt that in all mammals, including humans, early behavior in life is a result of the activation of structures that are largely a result of genetic endowment (Plomin et al. 2014). However, human behavior is highly flexible in its expression, and humans appear to have a much greater latitude for learning than other animals as seen in, for example, our many and complex languages. Each person’s behavior is made up of the evolutionary past embodied in the genetic apparatus and of the experiential past incorporated in the various forms of specialized brain mechanisms formed by evolution which include mechanisms dependent on environmental input such as learning and memory. As a consequence, another factor that has also to be considered is *culture*, variation caused by learning from other humans both past and present, facilitating a population’s adjustment to a given environment. Human nature is, therefore, a result of the interaction between genes and culture, known as biocultural evolution (Gintis 2011).

The human organism is an integrated and coordinated system, adapted to its environment, and at the same time, a member of a population with a unique evolutionary history adapting it to the environment it presently occupies. Because the evolution of the psychological mechanism’s underlying culture was so powerful, they resulted in cultural change (Mesoudi et al. 2004). As such, the transformation of sociocultural systems can best be explained via analogy to the synthetic theory of biological evolution, applying concepts as variation, selection, and adaptation. With that in mind, in this chapter, we discuss how the interactions between genetic evolution and cultural evolution, i.e., biocultural evolution, have shaped human nature. Before going further, understanding the concept of culture and how culture has

evolved throughout humans’ evolutionary past is an essential step to a comprehensive understanding of the nature and diversity of human behavioral adaptations.

A multifaceted process like culture is complex to conceptualize using one single definition; however, in this chapter, we will consider culture as a set of information that impacts individuals’ behavior and is acquired from other members of their species through teaching, imitation, and other forms of social transmission (Richerson and Boyd 2005). Culture here is considered as an autonomous inclusive fitness-seeking adaptive system that functions to maximize inclusive fitness under present-day conditions (Tooby and Cosmides 1989). According to Tooby and Cosmides (1992), our evolved information-processing mechanism should be context dependent in a way that different informational inputs should generate different behavioral and representational outputs, usually as an adaptive response to different environmental contexts. As a result, although humans share the same evolved information-processing mechanisms, people living in different areas or experiencing different environments can display different responses that may be adaptive under those different conditions.

Culture affects the success and the survival of individuals and groups; as a result, some cultural variants spread, and others diminish, leading to evolutionary processes that are every bit as real and as important as those that shape genetic variation. These culturally evolved environments can then also affect which genes are favored by natural selection. Over the evolutionary long haul, it has been argued that culture has shaped our innate psychology as much as the other way around (Richerson et al. 2010). According to Ruyle (1973), selective pressures result from the material conditions of life and of the society influencing individual members of a population which then determine both the genetic and cultural heritage of humans. Thus, the genetic characteristics humans share in different degrees with other members of their species along with psychological principles that have evolved genetically constitute the heart of “human nature.” As such, the

most fundamental question of how humans came to be what they are can be answered by considering culture as intimately intertwined with other aspects of human biology.

Genetic evolution created a psychology that allows the cumulative cultural evolution of complex cultural adaptations. One classic example relates to the coevolution of genes related to lactose digestion and the cultural practice of acquiring dairy products from other animals. Although the cultural evolution of animal husbandry practices emerged in at least two geographical locations independently, detailed genetic studies demonstrate that different genes evolved to generate tolerance to lactose in adults in each case (Ingram et al. 2007). It may have been the case that the evolution of dairy farming traditions increased the relative fitness of the gene that allows whole-milk consumption by adults in each environment. As that gene spread, it may have changed the environment, shaping cultural practices, perhaps favoring more milk consumption and as such tolerance to lactose (Richerson and Boyd 2005). This example illustrates how biocultural evolution operates to shape different human traits.

Likewise, biocultural evolution has been believed to have also played an important role in the genetic evolution of human psychology. While natural selection shaped variation, different modalities of transmission biases mold the distribution of cultural variants. To illustrate, we will borrow the example given by Richerson and Boyd (2005) regarding the development of language. It is indisputable that the human vocal tract and auditory system have been modified to enhance our ability to produce and decode spoken language and along with a special-purpose psychological machinery for learning the meaning of the words and grammatical rules. Selection, however, could not have shaped those in an environment without spoken language. The most plausible explanation is that simple culturally transmitted language arose first and then selection favored a special-purpose morphology and psychology for learning, decoding, and producing speech.

To explain how coevolutionary processes occur, Cloak (1975) proposes an ethological

model to understand the interaction between culture and biology: Cloak divided culture in two components that mutually influence each other: (1) *i-culture* that is a set of cultural instructions we carry in our nervous system and (2) *m-culture*, which encompasses the material instructions, including features of human behavior, technology, and social organization. Natural selection would, in turn, operate to shape cultural practices. Those cultural instructions whose behavior (m-culture features) helps to determine its occurrence, replication, or endurance in several places would therefore survive and propagate. Thus, the evolution of both genes and culture is governed by natural selection, which means that different environments will lead to different culture types, just as they can lead to different genotypes (Richerson and Boyd 2005).

Conclusion

Human nature is a controversial concept. Some thinkers have claimed that there is an innate human nature, emphasizing biological aspects governing behavior. Others have defended the idea that humans are unique and able to take decisions that are not governed by their biology and that humans are molded along their lives in interaction with the surrounding environment. There are also those who have advocated that there is no such thing as human nature and that the term should be abolished (Visala and Fuentes 2015). In this chapter, we highlighted that a biocultural view on human nature that resolves the nature versus nurture debate and considers the capacity for the interaction between biological factors and cultures is the key to understand what makes us unique.

In light of these arguments, we can conclude that any attempt to understand how humans came to be what they are that disregards either biological or cultural factors may fall into reductionism. Human beings are too complex to be understood based solely on one or another cause. A more comprehensive approach is one in which the role of both genetic and cultural

factors and their interaction contribute to human evolution resulting in what we can call human nature.

The deliberate or purposeful additions to the human body/anatomy, including clothing choice, jewelry, and various forms of body modification.

Introduction

Humans have always showed a propensity toward ornamenting ourselves. From an evolutionary perspective, ornamentation leads to unique gains in the mating market – allowing individuals the ability to bolster their appearance to potential partners by using environmental cues. Ornamentation can exist in a multitude of forms; clothing, jewelry, and even tattooing/piercing the body. Yet, all forms of ornamentation share one very important criterion in common: they are all cultural artifacts. Much of our evolutionary history has deep cultural roots across the world. The mechanisms of evolution shape many of our behavioral tendencies, including our capacity for culture and cultural artifacts (i.e., the way we ornament ourselves).

In the time long before written record, we made relics of elaborate adornments, hinting at an interesting unfolding of development within our uniquely human psyche. Before the Phoenician's paved the way for modern

language, humans were already pro's at creating ways to ornament ourselves; each culture (and various subpopulations within) unique, with types and levels of ornamentation varying in permanence. The headdresses of Native American's, the armor of a samurai, the makeup of a geisha, the stacking neck rings of numerous cultures, and full-body tattoos are just a few examples of the ubiquitous nature of body ornamentation. This human universal – the push to ornament oneself – is rooted in evolutionary theory. In proximate terms, it allows an individual to stand out in a crowd, and, depending on type of ornamentation, signal to a potential mate underlying fitness (in a way, it could be considered an extended phenotype). Nonpermanent forms of ornamentation like clothing have practical proximate outcomes: Ornamenting oneself in decorative clothing that either accentuates form or signals financial status can attract the attention of potential mates in a general sense. More permanent forms of ornamentation, like the neck-rings of the Padaung women, or full body tattoos not only promote uniqueness but also are a form of costly signaling. If an individual is able to successfully “pull off” a more permanent form of body ornamentation without any deleterious side effects, they are essentially self-handicapping (Zahavi and Zahavi 1997). This will be further expanded upon in the body modification section.

The Conscious Ape

At the heart of our complex system of body ornamentation lays a spark of consciousness that glows brighter than any other animals on Earth – including our closest living ancestors, the Chimpanzees. Our higher-order thinking quite obviously stems from their ancient thought processes, yet consciousness is something that had classically been considered uniquely human. Being able to be conscious of *oneself* (i.e., “have an identity”) and further, to understand that ones' own experiences are different from the next person, has allowed humans to excel in ways that no other animal has before us. Yet, it is important to keep in mind that humans did not just wake

up one day suddenly conscious of themselves; Evolutionary theory claims that in order for a structure to evolve, mechanisms will only build upon/shape lasting structures. Nonvocal forms of language within various types of great apes (especially chimpanzees) have been demonstrated many times over the past few decades (which hints at the idea of a common ancestral mechanism that was further shaped and built off of). This connection with symbolism (through language) arguably leads way to the idea of *consciousness* – which was classically thought of as a uniquely human attribute.

In 1977 Gallup Jr. demonstrated the bidirectional properties of consciousness in a sample of chimpanzees. Consciousness can be broken down into two streams: the outward stream (attention directed toward environment/surroundings) and the inward stream (the thought processes within your own mind) – hence, *bidirectional*. As many pet owners can attest, when cats and dogs are presented with their own reflection, they either do not seem to care at all or look into their reflection as if they are seeing another animal for the first time. In chimpanzees, this is not the case. Interestingly, recognizing your own reflection can indicate an evolutionary step in the formation of consciousness. When wildborn preadolescent chimpanzees were given access to mirrors, they were startled at first, but then began using the mirror to groom themselves in areas they could not normally see, or pick food out of their teeth – or even make faces at their reflection. After nearly 2 weeks of mirror exposure, the chimpanzees were anesthetized and a bright red mark was painted on their forehead. They recovered without a mirror in their cage, but once the mirror was re-introduced they immediately noticed and began touching the colored spot on their head, supporting the idea of self-awareness and essentially, a more simplistic form of consciousness in our closest ancestors. Unlike many other species (including many other primates), chimpanzees reacted to their own reflections and supported the idea that they hold part of the evolutionary building blocks that make up our consciousness. Human uniqueness is arguably due to our higher-order forms of consciousness, and through

that form of consciousness, human ornamentation was born. As the most conscious animal on this planet, it should not be surprising that we display some of the most complex forms of ornamentation.

The Building Blocks of Human Ornamentation: Behavioral Modernity

As mentioned earlier, evolutionary theory teaches us that for any structure to evolve or become specialized, it must build off a more basic form. Essentially, the birth of symbolic thought is linked to our drive to ornament ourselves and thus, when we became truly “human” is when we began forming these symbols of our culture. Approximately 200,000 years ago anatomically modern *homo sapiens* were already roaming across much of the old world, yet, signs of modern human behavior did not emerge for another 150,000 years. According to “The Human Revolution” reconstruction of human evolution, anatomically modern *Homo sapiens* experienced an exceptional shift between 40,000 and 50,000 years ago that marked the birth of behavioral modernity (signs of behavioral modernity include planning ahead and effectively using/manipulating resources) (McBrearty and Brooks (2000)). Some opponents of this model claim that modern human behavior was a structure that was slowly built upon, starting around 300,000 years ago and sculpted over hundreds of thousands of years. From this perspective, the transmission of cultural (and not genetic) processes over the course of many years is what eventually led to the culmination of behavioral modernity. Again, we see this strong link between body ornamentation and culture or cultural transmission. Yet, regardless of which model one ultimately sides with, we see a dovetail of modern human behavior and the birth of symbolic thought (along with body ornamentation).

Apart from the general idea of behavioral modernity, *Theory of Mind* is important to consider when attempting to understand human ornamentation from an evolutionary perspective. At a basic level, *Theory of Mind* is the ability to

attribute mental states to not only oneself and others but to recognize that other individuals might not share the same views as you. Similar to the idea of consciousness, being able to effectively rationalize that *I* is separate from *you* can lead to evolutionary advantages that play out in the form of human ornamentation. If an individual is ornamenting themselves in ways that are considered “attractive” culturally and socially, they are taking in cues from their environment, processing them, and providing an output via ornamentation that will potentially increase their reproductive success (due to the ornamentation practices being seen as “attractive”).

Some of the earliest examples of body ornamentation are perforated shell beads found in Africa. These beads date back 150,000 years – after anatomically modern humans, but before the proposed shift to behavioral modernity. This early form of body ornamentation is a testament to the snowball effect of evolution; ornamentation was essentially once shells with holes and today takes a multitude of forms that can affect an individual’s phenotype on numerous levels (i.e., extended phenotype). Remember, a phenotype is typically explained in terms of being the physical expression (or output) of a genetic code. All living things are essentially vehicles for our genes: transporting them throughout the generations via sexual reproduction. Yet, the reach of our genes is not limited to our own bodies; it can actually extend out into the environment itself via behavioral manipulation (Dawkins 1999). Nonhuman examples include beaver dams and birds’ nests; human examples can include everything from clothing and houses to more extreme forms of ornamentation like piercing, tattooing, and scarification.

Group Membership

From an evolutionary perspective, human ornamentation is essentially used to increase the potential for reproductive fitness. One way to enhance reproductive fitness is via group membership. Since we are ultimately self-interested, the formation of groups was necessary in order

to control various levels of coercive power within different populations. Ancestrally, we went from small communities that averaged approximately 150 individuals to living in cities with populations of over a million. As the population began to grow exponentially, ornamentation practices became more ornate and elaborate to meet the demands of large communities.

The Human Canvas and Upping the Ante

The evolutionary forces that nudged us into groups also encouraged the cultural behavioral output of human ornamentation. Though human ornamentation has many outputs, one of the most fascinating is tattooing due to its permanence. *The human canvas* hypothesis is based on the idea that our propensity for symbolic thought and our need to be unique from one another lead to an explosion of creativity that began on the walls of caves but eventually turned to our skin (Carmen et al. 2012). The subject matter and placement of a tattoo can either enhance or impede an individual's likelihood of getting approached by a potential partner.

As populations began rising and healthcare became more advanced, ornamentation practices became more costly to meet this demand. In many cultures across the globe, we see tattooing and piercing in the general population. Because of large modern populations, individuals must *up the ante* in order to stand out to potential mates by means of costly signaling, often doing so via tattooing and piercing (Carmen et al. 2012). The more elaborate or specialized the tattoo or the more unique the piercing, the more costly and potentially attractive.

Of course, ornamentation is not typically permanent. In fact, it can often be used to signify a momentary emotional state or to enhance a specific feature depending on what an individual wishes to highlight, specifically when it comes to cosmetics. The type of ornamentation can vary drastically within and between cultures. Black pigment referred to as *kohl* was used as eyeliner in ancient Egypt and much of the Arab world. In India, Henna (dye) is used to make complex

designs on the skin, outlining the fingers and highlighting certain areas of the wrist, and in Japan, geisha wore rice powder to paint their faces white. Cosmetics were used historically and cross culturally as a way to enhance appearance, ultimately aiding individuals in finding a mate.

Modern Ornamentation

In today's society, cosmetics, clothing, tattooing, piercing, shoes, and hairstyles can all be ways in which individuals ornament themselves. Though some forms of ornamentation are "dishonest" in nature (think waist trainers, magnetized piercings, and spray tans), they are all momentary and can be removed in one way or another.

The plastic surgery industry prides itself on the quality of the (mostly permanent) ornamentation it provides to individuals. If people are unhappy with the way they look, they can change their phenotype if they have the cash to pay for it. A few years ago, there was a case in China where a man sued his wife for essentially having unpleasant looking children. It turns out that she apparently had plastic surgery prior to their marriage that he was unaware of, and their children looked like the mother's genotype, not her current phenotype. Plastic surgery is perhaps the most extreme yet discrete example of body ornamentation. Of course, there are many forms of body modification that are considerably extreme, but individuals that commit to these acts are often fully committed in that everyone knows they are. If plastic surgery is done well, no one will know (that is, unless they reproduce and their offspring look drastically different from them).

Conclusion

Body ornamentation has many faces in many cultures across the world and across time. As complex animals, we have always had a propensity to ornament ourselves in increasingly novel ways. As we grow and learn, it will only be a

matter of time until we find new ways to ornament ourselves, though, ultimately, we will always use an ancient algorithm to push us forward.

Human Precopulatory Sexual Conflict

Gregory Gorelik
Austin, TX, USA

Introduction

In sexually reproducing species, some degree of cooperation between the sexes is an inevitable result of the dependence of each sex on the other for reproduction. Some degree of conflict should also be expected, however, because each member of a reproducing pair has conflicting genetic interests. This conflict is termed “sexual conflict” and is responsible for the evolution of an arms race, or antagonistic coevolution (Rowe and Day 2006), between the sexes, whereby the evolution of offensive and defensive adaptations in one sex creates the selection pressure for the evolution of counter-adaptations in the other and so on.

The two major categories of sexual conflict are “intralocus” and “interlocus” sexual conflict (Parker 2006; Rowe and Day 2006). Intralocus sexual conflict describes the contradictory effects of two autosomal alleles at a particular genetic locus within an individual. For example, males are usually physically stronger than females due to the selective effects of male-male competition on size and strength (Frontera et al. 1991). Conflict may therefore occur between a male-linked allele associated with greater physical strength and a female-linked allele associated with lesser physical strength. Interlocus sexual conflict describes conflict between sex-linked genes at different loci, usually manifested as conflict between the reproductive strategies of individual males and females. Both types of sexual conflict can be *precopulatory* (i.e., occurring prior to mating).

Human Paleontology

- [Paleoanthropology](#)

Precopulatory sexual conflict describes the costs that individuals of one sex inflict on individuals of the other sex prior to copulation. This is the period during which males and females are typically evaluating the suitability of their prospective mate(s). Because females invest more physiological and behavioral resources in childcare (Trivers 1972), they evolve strategies aimed at securing more parental investment from males than males are willing to apportion. Males, on the other hand, evolve strategies aimed at avoiding parental investment in favor of pursuing casual sexual encounters with multiple females. Therefore, much of precopulatory sexual conflict consists in the tension between female reluctance and male eagerness to engage in sexual intercourse.

Sexual conflict may create opportunities for sexual cooperation. For example, when male aggression is correlated with genetic worth or ability to secure resources, it may benefit a female to mate with a male exhibiting aggression even if he harms her in the process. The reason for this is that any son sired by such a male will likely inherit his father's traits (Eberhard 2005). If the son's aggression helps him to spread his mother's genes, such a benefit may outweigh a prospective mother's cost of mating with an aggressive male. Even if females are only benefited by male aggression because other females find aggressive males more attractive (a phenomenon referred to as the "sexy son" hypothesis; see Gwinner and Schwabl 2005), a female preference for aggressive males may evolve. According to Eberhard (2005), instances of sexual conflict may provide "the original 'nudges' that set off rounds of traditional Fiesherian runaway female choice" (p. S21). Thus, what may be an instance of sexual conflict may actually be, either in whole or in part, an instance of sexual cooperation. Albeit speculative, the courtship rituals of some species may reflect such conflict-turned-cooperation scenarios, as suggested by the manner in which a female resists a persistent suitor only to accept his advances once he has "proven" himself worthy (see Crean et al.'s 2000, discussion of female mate choice for large males in contexts of premating struggles between male and female seaweed flies). Another possibility is that male aggression is, in fact,

costly to females, but the costs pale in comparison to the costs of resistance, which may involve harm or even death. As such, instances of sexual conflict may contain some degree of compromise and cooperation (Crean et al. 2000; Crean and Gilburn 1998; though see Parker's 2006, discussion of the decreased theoretical and empirical likelihood of sexual "concurrence" in comparison to sexual conflict).

Sexual Conflict Before Puberty

Sexual conflict pervades the entirety of the human lifespan. Even children and juveniles experience its effects. A good example of this is the practice of "*sim-pua*" marriages in Medieval China. *Sim-pua*, or "little daughter in law" practice, involved the adoption of a young, prepubescent girl by the parents of an infant son. The fact that such marriages were often unsuccessful is often presented in evolutionary discussions as an example of the "Westermarck effect" (Wolf 2005), which describes the activation of evolved incest avoidance mechanisms that prevent individuals who grow up in the same household from being sexually attracted to one another. *Sim-pua* marriages are also a good example of sexual conflict between the reproductive interests of male children and female children. Insuring the virginity and betrothal of a prospective daughter-in-law to one's son may have conflicted with the reproductive interests of the daughter-in-law if the son in question was of low genetic worth or if he and his family were less wealthy than they claimed to be.

Similar conflicts may occur in cultures that practice bride pricing and dowries. For example, parents who are vying for the betrothal of their son or daughter to a girl or boy whose parents are asking for a bride price or dowry may exaggerate the actual worth of their son or daughter (who may turn out to be unhealthy, unkind, or lazy) or their resources (e.g., the livestock turn out to be sick, the land turns out to not be arable). In such instances, the reproductive interests of a girl may already be in conflict with the reproductive interests of a boy, even if those interests are represented by parents rather than the boy or girl

in question. In effect, shared genes – and, hence, shared reproductive interests – among family members allow sexual conflicts between individuals to expand into conflicts between families.

An intriguing possibility is that unique imitative and linguistic abilities allowed humans to erect entire cultural systems as extended phenotypic expressions (see Dawkins 1982) of sexual conflict. In aforementioned examples of *sim-pua* marriages, dowries, and bride pricing, cultural traditions and explicit and implicit rules, norms, and principles are passed down alongside biologically older adaptations for sexual conflict. Certain Middle Eastern and African cultures, for example, enforce strict codes regulating interactions between men and women. Usually, the heavier burden is placed on girls and women. A girl who speaks to the wrong boy or a woman who wears something immodest is risking being harmed and even killed by a father, brother, husband, or entire community for having violated a law or tradition. An example of a more harmful cultural manifestation of sexual conflict is female genital mutilation, a cultural practice aimed at limiting a girl's sexuality by associating intercourse with excruciating physical pain. Effectively, such cultural traditions may be examples of society-spanning expressions of male adaptations for sexual conflict. Although a young girl and her parents perceive the alternative as much worse (i.e., prohibition from marriage and possible excommunication), female genital mutilation may nonetheless be situated in a context that favors male reproductive interests such as sexual proprietariness and decreased cuckoldry risk stemming from female pain during intercourse (Wilson and Daly 1998, 1993).

When examining such examples of culture-spanning sexual conflict, it is important to note that male adaptations to sexual conflict might benefit some women (e.g., the male's female kin; Gwinner and Schwabl 2005) just as female adaptations to sexual conflict might benefit some men (e.g., the female's male kin). Thus, it is no surprise that women often enforce restrictions and punishments on girls and other women in cultures advocating female decency (BBC Monitoring 2016), just as it is no surprise that men enforce the

criminalization and punishment of rapists and domestic abusers in cultures that value women's rights. This point also highlights the importance of not thinking of sexual conflict as a dualistic struggle between all men and all women. Humans are genetically heterogeneous creatures who can compete and cooperate with others regardless of their biological sex. As such, sexual conflict and its cultural expressions are simply the manifestations of the reproductive interests of individuals and not some universal patriarchies or matriarchies. From an evolutionary perspective, adaptations to sexual conflict are built by the differential survival and reproduction of individual men and women rather than by all men outcompeting all women or vice versa.

Sexual Conflict After Puberty

Men's sexual eagerness and women's sexual reluctance. The conflict between male eagerness and female reluctance to engage in casual sexual encounters is most clearly on display in a now classic study by Clark and Hatfield (1989). In the study, female college students were randomly approached by a male confederate, and male students were randomly approached by a female confederate who made various sexual propositions, ranging from less explicit (i.e., "Would you go out tonight?") to more explicit (i.e., "Would you go to bed with me?"). (Note that male and female confederate attractiveness was controlled for.) Unsurprisingly, all women refused the more explicit sexual offer, whereas a majority of men accepted it. It is easy to interpret Clark and Hatfield's findings in terms of sexual conflict dynamics. Specifically, by engaging in casual sex with the wrong man, a woman risks getting pregnant and being abandoned by the man – an outcome whose time and energy costs weigh heavily on the woman and her future offspring. A reluctance to engage in casual sex therefore evolved as part of women's arsenal in sexual conflict with men. Men, on the other hand, are reluctant to pass up any sexual opportunity, as doing so might jeopardize their reproductive

interests – which are marked by increasing the quantity, as opposed to the quality, of sexual partners.

Men's eagerness to engage in sexual behavior is often in conflict with female reluctance. According to Haselton and Buss's "error management theory" (Haselton and Buss 2000), men are expected to maximize realized sexual opportunities and minimize missed sexual opportunities. In practice, this leads to men's overperception of women's sexual interest, even if it is nonexistent. Such overperceptions were responsible for an eventual lawsuit on the part of women employed at the Safeway supermarket chain who were told to smile and act friendly toward all customers (Haselton 2003). The problem was that some male customers interpreted the female employees' friendliness in sexual terms, which led to many awkward and a few relatively serious consequences, such as harassment. Along similar lines, Abbey (1982) revealed that male participants are more likely than female participants to report sexual intent in an actress's performance (but see Perilloux and Kurzban 2015, for an alternative interpretation of error management theory).

Women must also contend with error management, but their dilemma concerns maximizing opportunities to find a committed long-term partner and minimizing the possibility of falling for – and possibly getting pregnant by – men who are not interested in commitment or paternal care. In practice, women realize this strategy with an enduring skepticism toward men's professions of love, devotion, and commitment (Haselton and Buss 2000). Men can presumably override this skepticism only if they lavish a sufficient amount of material and emotional investment on women to prove their honorable intentions. Inevitably, however, some men who are truly willing to commit are often passed over by women too skeptical to accept their shows of devotion as being genuine. Thus, women's underperception of men's commitment is often in conflict with men's eagerness to profess commitment (whether actual or false) in order to obtain or maintain sexual access to women.

In the context of romantic relationships, men's sexual eagerness and women's sexual reluctance

manifest itself in sex differences in the preferred timing of sexual intercourse (Buss and Schmitt 1993). In general, a man is ready to have sex a week or so after first meeting a woman. Women, however, only reach the point of sexual readiness about 6 months into the relationship. This difference in the preferred timing of sex probably leads to many instances of precopulatory sexual conflict marked by men's pressuring of women into sexual activity and women's prolonged reluctance to acquiesce. Such divergent sexual strategies also fuel men's increased interest both in pornography and prostitution (Ellis and Symons 1990; Schmitt 2003), both of which may exacerbate existing tensions within a relationship by causing women to question men's level of commitment. On their part, women's increased interest in romance novels and films may create unrealistic expectations for men by causing women to demand greater displays of love and commitment than their partners can provide, which only adds to men's costs of pursuing sexual relationships with women.

Deception in the mating market. Sexual conflict in human mating often centers on men's and women's mate preferences. One such preference is the desire for physically attractive mates (Buss 1989; Jones et al. 2001). Other preferences include a desire for mates who have resources and a desire for mates who are capable of long-term romantic commitment (Buss 1989; Haselton et al. 2005). Evolutionarily, attractiveness is associated with genetic health and fertility (Jones et al. 2001; Pflüger et al. 2012). When judging the physical attractiveness of prospective mates, individuals are specifically attuned to features such as symmetry, averageness, clear skin, voluminous hair, and youthful eyes (Apicella et al. 2007; Fink et al. 2008; Gangestad et al. 1994; Mesko and Bereczkei 2004; Peshek et al. 2011). All of these features can be passed on to offspring and are the most prize-worthy outcomes of short-term mating, reproductively speaking. Having resources may likewise be associated with having good genes, but is also associated with being able to provide for one's offspring. Similarly, being willing to commit to, or form a pair-bond with, a romantic partner signals a prospective partner's

willingness to stick around long enough to invest in any resultant offspring. As such, the ability and willingness to invest resources in one's partner and one's offspring are characteristics that are usually sought for in long-term mates.

Males tend to pursue a short-term mating strategy to a greater extent than females (even though the males of some species, such as human males, do invest in long-term mating and paternal care) (Trivers 1972). This is why men are generally more interested in prospective mates' physical attractiveness than are women (Buss 1989), whether in short-term or long-term relationships. Men's mate preferences focus on women's physical features such as youth, breast size, lumbar curvature, a 0.7 waist-to-hip ratio (i.e., an "hourglass" shape), and facial femininity (Burriss et al. 2011; Buss 1989; Karremans et al. 2010; Lewis et al. 2015; Zelazniewicz and Pawlowski 2011). Whereas women are generally more interested in long-term relationships and value characteristics such as maturity, ambition, industriousness, kindness, and commitment (Buss 1989; Buss and Schmitt 1993; Haselton et al. 2005; Lukaszewski and Roney 2010), they, too, engage in short-term mating and value men's characteristics such as height, masculinity, symmetry, and dominance (Gangestad et al. 2004; Pawlowski and Jasienska 2005; Penton-Voak et al. 2003; Quist et al. 2012). In general, women seek short-term mates either prior to finding committed partners or in order to procure good genes while deceiving existing committed partners (Pillsworth and Haselton 2006). In other words, sometimes a prospective mother's strategy may be to make sure that her offspring thrive in the genetic lottery regardless of who, if anyone, is providing paternal care.

When it comes to sexual conflict, men and women deceive each other about different things. This is suggested by Haselton et al.'s (2005) investigation into which types of deception men and women are differentially upset about. In general, men are more upset about women's false promises of sex (i.e., being "led on"), whereas women are more upset about men's exaggeration of their social status, resources, and willingness to commit. Although both short-term- and long-term-oriented men are upset about being led on,

short-term-oriented men experience greater discomfort over this type of deception, which is likely a reflection of their greater interest in casual sexual opportunities with multiple women. Women's greater distress over men's exaggeration of commitment and – especially for women seeking long-term mates – inflation of status and resources suggests that women are primarily interested in finding long-term mates who are able and willing to provide paternal care. In short, what Haselton et al.'s study suggests is that deception is an integral aspect of human precopulatory sexual conflict and that men and women deceive each other by pretending to cooperate with each other's reproductive strategies.

Intrasexual competition and sexual conflict.

When adaptations to sexual conflict are directed at other individuals whose behavior is likely to augment the reproductive success of an individual's would-be partner, it is helpful to consider this a form of *indirect* sexual conflict (see Thompson and Alvarado 2012, for a similar distinction between direct and indirect sexual coercion and the evolution of different adaptations in relation to each). All of the aforementioned examples constitute direct sexual conflict wherein males and females target their offensive and defensive adaptations at one another. Indirect sexual conflict entails that men and women target their attacks at their reproductive rivals. So, for example, when a male or female derogates or drives off an intended mate's other, otherwise valued, mating prospect, it can be said that the male or female is engaging in indirect sexual conflict. Although successfully driving off a competitor may indicate something about the successor's reproductive value, derogating rivals (which depends on cognitive and verbal abilities possessed by most humans) and seizing an opportunity to sabotage them (which depends highly on chance) are strategies that can be pursued by individuals of high and low reproductive value alike. Individuals of low reproductive value may even depend on these strategies to a greater extent than they do on strategies such as intrasexual physical combat and direct partner seduction – strategies that are more reflective of high reproductive value (see Miner et al. 2009b, for evidence that men of low

mate value may rely on cost-inflicting, as opposed to benefit-provisioning, mate retention tactics).

Direct and indirect sexual conflict are often indistinguishable, as driving away reproductive rivals of high mate value inflicts a direct cost on one's intended future mate. Sometimes, the cost is also felt by the individual engaging in such aggressive tactics, in which case it is a non-adaptive byproduct of sexual conflict or intrasexual competition. For example, the mere act of battling or driving off a reproductive rival may be fatal to a potential mate, as instanced by the occasional killing of a female red-sided garter snake, recently arisen from hibernation, by a pack of male garters that coil up into a swarm of aggressive reptiles wrestling one another in a destructive melee that crushes the fought-over female in its depths (Arnqvist and Rowe 2013, pp. 49–50). The distinction between direct and indirect sexual conflict is valuable, however, because anticipating the two types of conflict allows scientists to formulate testable hypotheses about specific adaptations that may have been differentially selected for either type.

One tactic that humans use to drive away reproductive rivals is competitor derogation (Buss and Dedden 1990). In general, men are more prone to disparaging a male rival's income and willingness to commit, whereas women are more prone to disparaging a female rival's looks and sexual behavior (Buss and Dedden 1990; Fisher 2004; Schmitt and Buss 1996). The reason for this is that women prefer mates who have – or have the potential to acquire – resources and who are willing to enter into a committed relationship, whereas men prefer mates who are attractive and, in the context of a long-term relationship, are sexually faithful (an important factor for men given the evolutionarily recurrent threat of investing in genetically unrelated offspring). By derogating competitors, men and women are essentially engaging in competition with their reproductive rivals by disparaging them to their prospective mates. This competition is not as extreme as a barroom brawl, but it is competition nonetheless, and may engage multiple cognitive adaptations.

On the one hand, if a derogator is correct about her rival's deficiencies (e.g., her rival is not as young as she claims to be), then this may be valuable information for her prospective mate, who may take appropriate steps to avoid mating with her rival. If the derogator is higher in mate value than her rival, then her derogation of her rival's age was an instance of cooperation between her and her prospective mate. On the other hand, if her rival is in fact as young as she claims to be, then the derogator is inflicting a cost on her prospective mate by denying him a reproductively valuable mating opportunity. Such instances of competitor derogation can therefore be considered as specialized weapons employed by men and women in the context of sexual conflict.

Various emotional adaptations are likewise aimed at deterring one's future or current mate from mating with, or investing in, one's reproductive rivals. One such set of adaptations is associated with the experience of romantic jealousy. In general, men are much more likely to experience sexual jealousy, whereas women are much more likely to experience emotional jealousy (Buss et al. 1992). Sexual jealousy is felt as discomfort at the prospect that an intended or current romantic partner has had sex with someone else. Men's greater susceptibility to this form of jealousy arises from their vulnerability to cuckoldry (i.e., an instance of a female having sex with a male who is not her long-term partner). Humans, along with only a few other species, are marked by both maternal and paternal care. In most cultures, paternal care is an essential component of the total care received by a child (though it still does not measure up to the level of care provided by mothers). As a result of the high cost of paternal care, natural selection designed various psychological adaptations to ensure that a man does not waste resources on genetically unrelated children. One such adaptation is sensitivity to any prospect of sexual infidelity, i.e., sexual jealousy. Due to the recurrent evolutionary costs of relationship abandonment and a redirection of resources to other women and their children, however, women are more prone to emotional jealousy, which is felt as discomfort at the prospect that

one's intended or current romantic partner has formed an emotional attachment (i.e., has fallen in love) with a reproductive rival. Both forms of jealousy may inflict costs on current or future romantic partners and can therefore be thought of as evolved, specialized emotions evoked in the context of sexual conflict.

As with many other sexually reproducing species, humans seek to neutralize their reproductive rivals by, among other methods, simply restricting their proximity to an intended mate, a technique known as "mate guarding." This can be done either by fighting off approaching rivals or by monitoring the movements of, or secluding, a prospective or current mate in order to make sure that he or she has no opportunity for a dalliance with a reproductive rival. Because males are typically stronger than females, they are more successful at mate guarding their prospective or current mate with threats and actual uses of force. Humans, for example, exhibit a continuum of mate-guarding behaviors, from benefit-provisioning, whereby individuals bestow gifts, care, and affection on partners in order to keep them happy, to cost-inflicting, whereby individuals inflict verbal and physical abuse on partners to deter them from ending the relationship or to punish them for actual or perceived infidelity (Holden et al. 2014; Miner et al. 2009a, b). Note that, although research on mate guarding mostly examines interactions within existing sexually active relationships (hence the term *mate guarding*), similar tactics can be employed by individuals prior to copulation.

Even though men and women engage in both benefit-provisioning and cost-inflicting mate-guarding behaviors, the costs of violent mate-guarding are mostly felt by women (Whitaker et al. 2007). Notwithstanding that men and women engage in similar levels of domestic violence (and, in some studies, women are actually shown to be the primary culprits; Whitaker et al. 2007), it is women who bear the most serious injuries, including death, as a result of a partner's abuse (Daly and Wilson 1998). This is unsurprising given men's greater physical strength, on average, compared to women's. Of course, some men are more reproductively successful than others,

and so they are expected to exhibit less jealousy and mate-guarding behaviors overall because they have no need of them. In partial support of this, tall men (who are high in mate value) exhibit less jealousy and engage in fewer benefit-provisioning mate-guarding behaviors (e.g., "love and care") than short men (Brewer and Riley 2009). Unlike short men, however, tall men engage in more cost-inflicting behaviors (e.g., monopolization of a partner's time). The authors hypothesize that this is because men of high mate value can more easily get away with guarding mates by engaging in costly mate-guarding behaviors, whereas men of low mate value might risk being abandoned by their partners if they were to engage in such behaviors. Other studies, however, suggest that men of low mate value are *more* likely to engage in cost-inflicting mate-guarding behaviors (such as verbal insults) than men of high mate value (Miner et al. 2009a, b).

Sexual harassment. Due to both methodological and political roadblocks, the evolutionary study of harmful sexual practices such as sexual harassment and sexual coercion continues to garner much controversy and debate. Nevertheless, notwithstanding the gap in our theoretical and empirical understanding of these phenomena, the evolutionary biological framework provides an important starting point for their scientific examination. However flawed the attempts at tracking harmful sexual behaviors through the lens of evolution by natural selection – and, in particular, the framework of sexual conflict – might be, such attempts are necessary if these behaviors are to be understood and remedied. As with any discussion of controversial topics with far-reaching social and political implications, it is important to keep in mind that any attempt at explaining such phenomena from a scientific perspective should not be conflated with an endorsement of them.

The definition of sexual harassment varies across time, region, and even across individuals. Nevertheless, its legal parameters within the United States often confine it to two more-or-less independent categories: (1) *quid pro quo* sexual harassment, which involves pressuring someone into sexual activity with either threats (e.g.,

the loss of employment) or inducements (e.g., job promotion), and (2) the creation of a hostile environment via the persistent expression of unwelcome explicit or implicit sexual content (e.g., sexual jokes, suggestive comments about someone's clothing, etc.). Note that, although these categories are not the final word on what constitutes sexual harassment (as both the legal and lay understanding of sexual harassment continue to change), they are sufficient starting points for a discussion of how sexual conflict can illuminate instances of coercive sexual behavior.

Because men are generally more prone to favor casual sexual encounters and to pursue promiscuous sexual strategies to a greater extent than women, it is predicted that they would be the primary sexual harassment offenders. And, indeed, they are. As cited by Studd and Gattiker (1991), women – especially women who are young and single – are overwhelmingly more likely to report being victimized by workplace sexual harassment than men, and men are almost always the perpetrators. From an evolutionary perspective, be it quid pro quo or hostile environment sexual harassment, the fact that men are the primary culprits suggests that sexual harassment is a manifestation of men's evolved propensity to maximize sexual access to as many women as they can. As such, sexual harassment is an example of sexual conflict because it often exacts costs on its recipients.

In cases of quid pro quo sexual harassment, women who do not acquiesce to sexual advances may risk the loss of resources if their job security or career prospects are threatened. Women who do acquiesce to such advances, however, may risk unwanted pregnancy or the possibility of exposure to sexually and nonsexually transmitted diseases as the costs of maintaining their employment or furthering their career. Similarly, women who encounter a hostile work environment may suffer both financial and psychological costs due to the loss of productivity and emotional security. It is also possible that women may suffer reputational damage if they are perceived to not be “team players” due to their not taking part in crude office banter or sex talk – damage that could threaten both their career and mating prospects.

That sexual harassment may be a manifestation of sexual conflict is evidenced by instances of similar conduct that is less likely to be perceived as harassment when exhibited by attractive or high-status individuals. In examining sexual harassment vignette ratings, for example, LaRocca and Kromrey (1999) found that college students rated sexual advances as being less harassing when coming from attractive opposite-sex individuals (e.g., female students rated attractive male professors as being less harassing than unattractive male professors). Similarly, female flight attendants reported less negative affective responses to verbal and physical sexual harassment exhibited by high-status pilots than by low-status airline workers such as cleaners and ticket agents (Littler-Bishop et al. 1982). These findings indicate that sexualized behaviors are only perceived as harassment when they are suggestive of sexual conflict – i.e., conflict between incompatible mating strategies. When there is no conflict, as when sexual overtures come from opposite-sex individuals who are of a high mate value, recipients are less likely to interpret such overtures as harassment.

Rape and sexual assault. The most extreme forms of sexual conflict are sexual assault and rape. Although women's sexual assault of men does occur, men's greater sex drive and women's decreased physical strength collude to make women's vulnerability to sexual assault and rape by men a more prevalent phenomenon. (Men's sexual assault and rape of other men are not presently discussed.) Furthermore, rape and sexual assault can be studied in the context of precopulatory sexual conflict because forced copulation need not occur for individuals' physiological and psychological adaptations associated with it, and in response to it, to be activated. For example, a man planning on committing a sexual assault in the future may very well be acting out a behavioral pattern that is a product of innumerable generations of sexual conflict between the sexes, even if the man happens to be arrested prior to committing the assault. Similarly, even if she is never attacked herself, a woman who is wary of strange men may be exhibiting a behavior pattern that was selected because it helped ancestral women to

avoid unwanted sexual attacks. Despite the lack of an actual rape, each scenario highlights the possibility that specific precopulatory mechanisms (i.e., the planning of a sexual assault in the former scenario and its avoidance in the latter) selected in ancestral contexts of sexual conflict may be at play.

Whether rape is an adaptation whose selected function is to allow men to maximize their reproductive opportunities is still a topic of contention for both scientific and political reasons. Nevertheless, the prevalence of forced copulations among nonhuman animals attests to its occasional evolutionary advantages (Palmer 1989), which necessitates its inclusion in discussions of human sexual conflict. According to McKibbin et al. (2008), human rapists can be sorted into at least five categories: disadvantaged men (i.e., men who rape because they have no other avenue for consensual reproduction), specialized rapists (i.e., men who exhibit specific physiological and psychological adaptations for rape, such as greater arousal to sexually violent stimuli and discriminatory targeting of rape victims), opportunistic rapists (i.e., men who only exhibit sexually coercive behaviors in contexts where doing so poses fewer punitive risks, as in warfare – see Chang 1997, and Morris 1996), high-mating-effort rapists (i.e., men who are otherwise sexually successful, but who rely on sexual assault to obtain reproductive access to unwilling partners – see Lalumière et al. 1996), and partner rapists (i.e., men who rape their romantic partner when under threat of sperm competition following a partner's actual or perceived infidelity).

If rape and sexual assault were a regular part of life for ancestral women, it is likely that women evolved counter-adaptations aimed at preventing and countering such attacks. Hypothesizing this, McKibbin et al. (2009) developed a “rape avoidance inventory” by extracting four principle components from women's ratings of various rape avoidance behaviors. Each of these components may reflect a suite of specific defensive adaptations, and the components are as follows: “avoid strange men,” which includes behaviors such as avoiding men with a reputation for sexual assault and not letting strange men into one's home;

“avoid appearing sexually receptive,” which includes behaviors such as avoiding wearing revealing clothes or drinking alcohol in unfamiliar places; “avoid being alone,” which includes behaviors such as turning on the television or music when alone and not going out alone; and “awareness of surroundings/defensive preparedness,” which includes behaviors such as looking around before getting out of the car and carrying a defensive weapon.

If the sexually coercive strategies on the part of men and the defensive strategies on the part of women constitute adaptive solutions to recurrent reproductive problems that members of each sex posed to members of the other sex over evolutionary time, then such solutions are examples of adaptations wrought by generations of sexual conflict. These strategies may even exhibit elements that are specifically tuned to the precopulatory period. For example, disadvantaged rapists and high-mating-effort rapists may exhibit adaptations specifically suited to assessing their own mate value and to responding to such an assessment by developing a sexually coercive mating strategy. Similarly, the development of specialized rape adaptations may depend on critical periods during which adolescent boys and young men are drawn toward, and positively rewarded by, violent sexual cues. In response, women may have evolved the ability to pick up on some of the specific cues given off by these men as a subcomponent of an avoidance-of-strange-men adaptation and may consequently avoid being alone or appearing sexually receptive when in the vicinity of these men. Opportunistic rapists may exhibit selective attunement to contexts wherein they could sexually coerce unconsenting women with impunity, and partner rapists may exhibit adaptive psychological and physiological precopulatory adaptations that are sensitive to contexts of partner infidelity and that bring about a more rapid sexual response as a result. In turn, women may discriminate between environments and contexts wherein they would be more or less vulnerable to rape and sexual assault and may modify their behavior accordingly. For example, women's awareness of their surroundings and attendant defensiveness may be activated in contexts wherein the costs of

men's sexual violence are low or when their partners suspect them of infidelity.

Women's antirape adaptations, such as avoiding strange men, avoiding appearing sexually receptive, avoiding being alone, being aware of one's surroundings, and being prepared to defend oneself, all occur prior to the onset of forced copulation. In addition to McKibbin et al.'s (2008) proposed suite of women's antirape defenses, Thornhill and Thornhill (1990) advanced evidence for the adaptive function of psychological pain such as fear and social disturbance following sexual victimization. Specifically, Thornhill and Thornhill report that women of reproductive age (as opposed to prepubescent and postmenopausal women) and married women experienced more psychological pain after being raped than women who were neither of reproductive age nor married. The authors suggest that this is because psychological pain following a reproductively costly event functions to redirect one's efforts toward preventing such events in the future and that the evolutionary costs of rape are greatest for women of reproductive age (who suffer from the circumvention of mate choice) and married women (who may suffer an increased risk of partner abandonment). As such, psychological pain following rape or sexual assault should likewise be counted as an adaptation for precopulatory sexual conflict, being as how it is aimed at preventing future instances of forced copulation.

Conclusion

The previous discussion suggests that much of human mating may be imbued with adaptations and counter-adaptations whose features were shaped by ancestral arms races between men's and women's competing reproductive strategies. Much is still unknown, however, about whether some of the previously mentioned examples – particularly with respect to instances of rape and sexual assault – indicate the presence of specialized adaptations on the part of men and women. It may be that, for example, men's proclivity for sexual violence is not adaptive in itself but is rather a byproduct of a more general male

proclivity for sexual variety. Likewise, women's antirape defenses may not be adaptive in and of themselves but may be extensions of more general defensive behaviors whose function is to ward off both human and nonhuman predators – behaviors that may be shared by both sexes. More research is needed in tracking both the evolutionary history of human sexual conflict and its physiological and psychological manifestations in modern humans.

Definitions

Human products represent goods (articles, items), ideas, methods, information, and services produced by humans.

Introduction

As sources of data, human products can be analyzed from the perspective of several inclusive fitness-related functions (inclusive fitness is referred here as the abilities of an individual to further pass its genes on to the next generations; Hamilton 1964). These functions can be centered on the individual physiological needs in the physical environment (e.g., clothing for the regulation of body temperature, food preparation, access to

water) on intraspecific interactions (couple, family, cultural groups and other types of institutions) or on interspecific interactions (e.g., human-animal interactions). Having in mind these multiple levels of functional analysis of human products as data sources and being aware that these levels are generally overlapping, a synergic frame of analysis of human products as data sources is proposed here in terms of identifying the connections of human products with individual, developmental, and evolutionary human motives. This synergic analytical frame integrates the model of the renovated Pyramid of Human Needs (Kenrick et al. 2010), the niche construction theory (Laland and Brown 2006, with references to the extended phenotype, Dawkins 1982), the idea of evolved aesthetic preferences (Miller 2001; Tooby and Cosmides 1990), and the principles of Positive Design applied to human products (symbolic meaning connected to subjective happiness and quality of life; Cassais et al. 2016).

Human Products as Indicators of a Pyramid of Human Needs

Maslow's Pyramid of independent sets of human needs (Maslow 1943; immediate physiological needs, safety, affection, esteem, and self-actualization) offers generous possibilities of interpretations of several aspects of human developmental and social functioning, including the human motivation to produce items, methods, and information (i.e., human products) corresponding to their needs.

A revised version of Maslow's Pyramid of needs is offered by Kenrick et al. (2010) in the light of theoretical development at the interface of evolutionary biology, psychology, and anthropology. The renovated Pyramid of Needs highlights the connections between fundamental motives and immediate situational threats and opportunities in human existence, hence anchoring the hierarchy of human motives in the field of modern evolutionary theory (Kenrick et al. 2010). The updated Pyramid examines human motives at three levels of analysis: (a) their ultimate evolutionary function; (b) their developmental

sequencing, and (c) their cognitive priority as triggered by proximate inputs.

The most important updated aspect of the Pyramid of Needs is the functional reconsideration of the self-actualization, which is not regarded anymore as a functionally distinct human need. Based on their new interdisciplinary framework of analysis, Kenrick et al. (2010) removed self-actualization from the top of the pyramid and subsumed it within status (esteem) and mating-related motives. In the process of the Pyramid's updating, the authors combined the development level of analysis with the biological framework of *life history theory*, which addresses the trade-offs between the organisms and their environment, in terms of how the time and energy should be allocated in activities and traits that have the potential to maximize their fitness (e.g., Kaplan and Gangestad 2004). Hence, the updated Pyramid includes the following fundamental human motives, starting from the base: (1) Immediate Physiological Needs, (2) Self-Protection, (3) Affiliation, (4) Status/Esteem, (5) Mate Acquisition, (6) Mate Retention, and (7) Parenting. One can notice that the top of the Pyramid contains three reproductive goals, appearing in their developmental order. The authors stress that the later developing goal systems are overlapping, rather than replacing earlier developing systems; once a goal system has developed, its activation can be triggered by salient relevant cues (Kenrick et al. 2010).

The updated version of the Pyramid of Human Needs and the three levels of analysis proposed by Kenrick et al. (2010) provide a frame for the identification of developmental, individual, and evolutionary data provided by human products.

Several human products are parts of tactics of benefit-provisioning behaviors, which "...are *mate retention behaviors that are intended to increase the incentives of staying mated to the current partner and, in turn, deter defection from the relationship. These behaviors can include things such as buying gifts for the partner, altering one's appearance, and different sexual behaviors*" (► [Benefit Provisioning](#)). From an evolutionary perspective, a wedding ring, for example, might indicate a resource display within

the positive inducement tactic, such as the ability of a partner to provide resources to the female and her offspring and/or intentions of emotional investment – love and affection – in the relation. Also, wedding rings may offer indications about another tactic within the benefit provisioning process, which is the possessive ornamentation, meaning that a male might offer a wedding ring (or another symbolic product) to his female partner to convey to same-sex individuals the status of the relationship (Holden et al. 2014). While a wedding ring can generally be associated with relationship status in nearly any type of human cultures, other forms of human products might be either more ambiguous regarding the information they convey or be presented with specific explanations to the persons expressing interest in the history of the product (e.g., the story of a scarf received as a gift from a former romantic partner in a specific moment of life).

If the example of the wedding ring is taken through the multilevel analysis framework provided by the updated Pyramid of Human Needs model (Kenrick et al. 2010), such an item may offer data on two reproductive human motives (mate acquisition and mate retention), but also on the status/esteem motive. Moreover, the acquisition of reproductive-related human products, such as wedding rings, for example, may offer data on the developmental stage of an individual. Hence, a man who purchases a wedding ring is at a sexual maturity stage rather than at an earlier stage of his ontogenetic development. The value of the wedding ring might offer data not only on the status/esteem of the person, but it may also indicate that a person who can afford to offer an expensive ring to a potential partner probably has no difficulties in terms of the fulfillment of the individual needs situated at the base of the Pyramid (i.e., immediate physiological needs: access to food, water, and shelter).

Human Products as Indicators of Niche-Construction Process

The idea of individuals changing the environment according to their contextual, developmental, and

evolutionary needs is a focus of the *niche-construction perspective* (Laland and Brown 2006). The interaction with the environment is considered bidirectional, in that organisms adapt to their environment and they also adapt the environment to their needs. Like other animal species that manufacture nests, holes, webs, burrows, etc., humans can change, adjust, and construct their physical and social environment. Laland and Brown (2006) point out that niche construction implies not only building environmental components, but regulating the environment “*to damp out variability in environmental conditions.*” Hence, human products may convey data on the environmental variability the humans are faced to and the solutions they came up to minimize this variability. The authors argue that niche construction is not an end product of evolution but a continuous cause of evolutionary change (Laland and Brown 2006).

The large variety and intensive dynamic of human products (including digital information) indicates that, compared to other animal species, humans appear to be effective niche constructors that are continuously challenged by the interaction between their cumulative culture and their evolutionary and developmental needs, as well by contextual threats and opportunities (see Laland and Brown 2006). Culture is seen here as “*the ability to acquire and transmit learned knowledge, beliefs and skills and to devise ever more efficient solutions to problems that build on this reservoir of shared knowledge*” (Laland and Brown 2006). While some human products can be interpreted as parts of the extended phenotype of individuals, based on the effects that the candidate genes for that type of product has on the environment (Dawkins 1982), there are theoretical studies (mathematical population genetics) indicating that niche construction does not have to be based on genes in order to impact the evolutionary process (Laland and Brown 2006). Hence, it is believed that human culture and the process of niche construction have become self-reinforcing and that the transgenerational culture changes the environment in a manner that favors more culture in order for the human beings to fulfill their needs.

Many human products (elements of the constructed environment), specifically ones that are related to the human motives situated at the base of the updated Pyramid of Human Needs (Kenrick et al. 2010), appear to be resistant to transgenerational culture, in that their basic characteristics indicate their original utilitarian function and that they are generally shaped to suit the human bodies (e.g., cups, forks, knives, clothing, socks, beds, chairs, doors). Typically, niche construction in humans can have immediate fitness benefits to the constructor or to those who acquire the products (Laland and Brown 2006). However, some human products (e.g., medical products, nuclear power plants) may have critical consequences for the environment, which can be translated into negative effects on human fitness. Hence, the presence of these types of products in a specific environment may offer data on the negative effects the products can bring to human individuals and other living species, but also on their potential as selective pressures.

Some human products can be transformed by the users according to their specific needs or body characteristics, e.g., a wheel chair can be adapted to the human body shape and posture and clothing can be adjusted to the length of the legs. Other products, even though they do not fit the personal preferences of the users in terms of aesthetic appearance and proximate needs, cannot be reshaped/adapted due to their built-in characteristics or because they represent unique art-work pieces.

The diversity of traits within the same utilitarian category of human products (variations in shape, color, size, etc.) has attracted a lot of interest toward the analysis of the *aesthetic qualities* of human products in relation to the evolved aesthetic preferences of humans. Such preferences are thought to be based on the aesthetic experiences of individuals while interacting with their environment (in a direction of favoring the inclusive fitness of individuals) and are supposed to be molded by natural selection through the adaptive advantages conferred by emotional responses during the process of problem solving and decision making in relation to elements of habitat (Orians 2001, in Hogh-Olesen et al. 2009). Besides the habitat selection-based explanation of human aesthetic preferences, Miller (2001) has introduced

an updated idea of the connection between human appreciation of beauty and mate-choice (Darwin 1874), arguing that many design features of art products may function as indicators of “*artist’s virtuosity, creativity, intelligence, conscientiousness and other important heritable mental and physical traits*” (Miller 2001 in Hogh-Olesen et al. 2009). In other words, Miller (2001) suggests that the aesthetic judgment can be part of the mate-choice process and social cognition, in that art-work can be seen as an extended phenotype of the artist (Hogh-Olesen et al. 2009). Also, the large variation within the same category of products allows individual aesthetic preferences to manifest at the level of decisions about purchasing one variation over others.

Many human products are nowadays a result of mass production (e.g., cups, glasses, makeup, clothing products, etc.) and their authors are individually unknown to the persons that are purchasing them. Hence, the decision to purchase a product may offer data on the needs of the user, his/her aesthetic preferences, and on the qualities of the product that match the search image of the user. However, in some cases, such as art exhibitions and fashion shows, the authors of the products reveal themselves to the potential buyers. In these cases, i.e., having some information about the persons behind the products, the users/buyers tend to pay more attention to the association between the psychosocial characteristics of the producers and the products, and the decision to purchase the product may be based on this association. Therefore, the labels of several successful human products (in terms of high demand on the market) may offer data not only on the quality of the product itself but also on the socially and economically perceived image of the producer. A highly expensive and rare brand can offer data on the socioeconomic status of the purchaser, thus functioning as a badge of status for the owner of the product.

Human Products as Indicators of an Evolved Aesthetic Preferences

From the perspective of “narrow” evolutionary psychology (e.g., Tooby and Cosmides 1990),

human aesthetic preference is considered a *single integral capacity* (or a genetically based set of beauty detectors, Kogan 1994), regardless of the mate-choice and/or habitat selection advantages it might have provided to our ancestors. Hence, one can infer that, besides their primary utility, human products may offer data on the personality-based and culturally-shaped aesthetic preferences of their users/owners and that the products a person is acquiring during specific moments of lifetime may be considered as elements of that person's extended phenotype. Besides the data on the aesthetic preferences of the user and on the human motives illustrated by the updated Pyramid of Human Needs (Kenrick et al. 2010), human products may also provide data on the personal significance of a product. The personal significance may or may not be related to the aesthetic preferences of the owner of the product.

Human Products as Indicators of Positive Design

Positive Design is possibility-driven design that enables positive experiences in the direction of improving human well-being (Desmet and Pohlmeier 2013). Several studies on symbolic meaning of human products in relation to Positive Design indicate that people from different cultures tend to attribute symbolic meanings to a large variety of products in association with their need for subjective happiness and personal comfort (e.g., Cassais et al. 2016). Human products with symbolic meaning can provide the users with the following additional functions (besides the primarily utilitarian function), most of them indicating individual context sensitivity (see Cassais et al. 2016): preserve memories, remind of goals of aspirations, and help build and signal identity (e.g., Csikszentmihalyi and Rochberg-Halton 1981). The products that are mostly accessible through specific stages of development (e.g., favorite toys during childhood) can be offered symbolic meaning in associations to those stages. These associations between products and specific stages of development may be recalled later in life.

While the process of decoding the personal symbolic meaning of a human product requires access to data based on self-reports (interview, content analysis of a diary, etc.), some products can offer direct cultural specific information (e.g., flags, badges, etc.). Physical characteristics of human products, such as their solid structure, for example, facilitate their preservation through long periods of time (e.g., cups, printed pictures, miniatures, carpets), which favors the construction of symbolic meaning. The symbolic meaning of a product is constructed by the owner of that specific product (in the direction pointed by the extended phenotype theory), meaning that without the communication of the meaning by the owner, the symbolic meaning may never be revealed to other persons. Some products, such as the personal advertisements, are produced and used for specific periods of time and their content offers clear indications on what individual need from a potential partner.

Personal Advertisements: Sources of Data about Mate-Choice Process

Overall, evolutionary psychologists consider mate-choice a negotiation process between two partners, and the way each sex expresses choosiness in the process of mating may vary across human cultures (e.g., Schmitt 2005; Rusu and Maxim 2009). Compared to other animal species, humans sometimes engage in forms of mate search in which they explicitly state what they have to offer to their potential partners and what they expect from them (e.g., Pawlowski and Dunbar 1999). One of the most common forms in which an explicit communication in this respect occurs is the market of personal advertisements, either online or via newspapers (Pawlowski and Dunbar 2001). A personal advertisement typically consists of a list of self-descriptive attributes (i.e., words describing the traits of the advertiser) and a list of attributes the advertisers seek in a prospective partner (Pawlowski and Dunbar 1999). Studies of the matrimonial market in different cultures indicate that the descriptive attributes contained in the personal advertisements reflect the gender-biased mate-choice strategies as predicted by

Triver's theory of parental investment (Trivers 1972), which states that the relative proportion of investment in rearing the offspring varies across males and females. This asymmetry regarding the parental investment of each sex is supported by the facts that a female needs fewer mating episodes to fertilize the eggs she can produce during the entire life, whereas a male has the potential to fertilize a much higher number of eggs than one female can produce. Trivers (1972) has argued that, because of this difference, the reproductive success of females tends to be limited by their access to resources needed for the nourishment of each of their eggs, while the reproductive success of males tends to be limited by their access to females. Given these conflicts of interests between the two sexes, it is expected that the mate-search strategies differ between males and females accordingly. There are numerous studies showing that women, as opposed to men, express a stronger preference for attributes referring to resources necessary for the survival and success of offspring developing from their fertilized eggs. Previous investigations indicate that some of the resource-related attributes that women generally seek are: financial wealth, social status, desire for children, and desire for commitment (e.g., Bereczkei et al. 1997; Buss and Schmitt 1993). Since all these attributes are age-dependent traits in men (i.e., older men in average have greater access to resources critical to female reproduction; Buss 1989), women usually seek older partners. Like the males of other sexually reproducing species, men commonly select their mating partners on the basis of cues that correlate with female fecundity, such as youthfulness, health, and physical attractiveness (Buss 1989; Pawlowski and Dunbar 1999).

Several investigations of personal advertisement markets indicate that these type of human products reflects the evolutionary principles of the theory of parental investment, i.e., male advertisers are more concerned than females about attributes that refer to their partner's fecundity, while female advertisers tend to focus on their future mates' wealth and commitment (Bereczkei et al. 1997; Pawlowski and Dunbar 1999; Rusu and Bencic 2007).

While personal advertisements indicate the proclivity of human individuals to form couples and reproduce, a specific category of human products (e.g., weapons), besides the utilitarian function of hunting animals for survival (food, clothing), indicates the potential of human beings to harm and kill other individuals with the help of weapons.

Human Products (Weapons) as Indicators of Intraspecific Aggression

Buss and Shackelford (1997) start their paper on the evolutionary perspective of human aggression with a reference on the usage of weapons by our ancestors, as indicated by ancient hominid skeletal remains (Trinkaus and Zimmerman 1982). From an evolutionary psychological perspective of human aggression, weapons, as human products and besides their hunting utility, can functionally fit within all the seven intraspecific adaptive problems proposed by Buss and Shackelford (1997) for which aggression might have evolved as a solution: (1) co-opting the resources of others, (2) defending against attack, (3) inflicting costs on same-sex rivals, (4) negotiating status and power hierarchies, (5) deterring rivals from future aggression, (6) deterring mates from sexual infidelity, and (7) reducing resources expended on genetically unrelated children. Within these aggression-related strategies, the individual decision to use a weapon and the need to purchase such a human product is context-sensitive. Besides the evolutionary psychological explanations listed above (which can be associated with the presence of weapons in human existence), and like other types of human products, weapons may offer data on several other dimensions. These include the degree of mastery a person needs to acquire in order to properly use the product, the aesthetic preference of the user, the possibility to be used by a sole person or if it requires cooperative work, and the degree of innovation of the producer.

Conclusions

Many human products appear to be shaped to suit human bodies and to serve human basic needs (immediate physiological needs), while others seem to be associated with individual, intraspecific, and interspecific needs (with all their proximate, developmental, and adaptive aspects and inferences), such as self-protection, affiliation, status/esteem, mate acquisition, mate retention, and parenting. From the perspective of niche construction theory (see Laland and Brown 2006), human products may offer evolutionary relevant data on the potential of human individuals to control the variability in environmental conditions, in the direction of maintaining specific conditions within tolerable limits for their survival and reproduction, which are the two dimensions defining the evolutionary inclusive fitness. Additionally, the decision to purchase a product may offer data on the needs of the user, his/her aesthetic preferences, and on the qualities of the product that match the search image of the user. A synergic framework for the analysis of human products as sources of data is proposed here, by integrating the model of the renovated Pyramid of Human Needs (Kenrick et al. 2010), the niche construction theory (Laland and Brown 2006, with references to the extended phenotype, Dawkins 1982), the idea of evolved aesthetic preferences (Miller 2001; Tooby and Cosmides 1990; Kogan 1994), and the principles of Positive Design and symbolic meaning (Cassais et al. 2016). Also, the behavioral flexibility and context-sensitivity showed by human individuals (Buss and Shackelford 1997) should be always taken into account in the process of identifying the potential functions and significance of human products.

Human Self-Domestication

Definition

A longstanding evolutionary process of human sociosexual selection for reduced reactive aggression, leading to correlated behavioral, physiological, and morphological trait changes consistent with “domestication syndrome” as seen in domesticated animal lineages.

Introduction

Domesticated animals are known to show a range of correlated trait changes in common when compared to their wild ancestors or relatives (Leach 2003; Wilkins et al. 2014; Zeder 2015). These traits have been experimentally demonstrated to emerge in response to sustained breeding selection for less reactive aggression (Trut et al. 2009). Modern humans show similar changes when compared to fossil remains of earlier *Homo sapiens* (Cieri et al. 2014). This evidence, coupled with high levels of cooperation and sociability, has led multiple authors to diagnose a process of “self-domestication” in human evolution (Cieri et al. 2014; Hare 2017; Leach 2003; Thomas and Kirby 2018). Human self-domestication is thought to have substantially enhanced our capacity for amicable social interaction, promoting language acquisition, shared culture, and technological capacity.

Domestication Syndrome

Domesticated lineages are known to show a syndrome of correlated traits in common when compared to their non-domesticated ancestors or relatives (Leach 2003; Wilkins et al. 2014).

These traits typically include behavioral docility (especially dampened reactive aggression); reduced sexual dimorphism; smaller brain sizes; lower skeletal robusticity; smaller teeth; floppy ears; pedomorphic morphology, physiology, and behavior; earlier sexual maturity; nonseasonal estrus; less prognathism; and altered pigmentation (Leach 2003; Trut et al. 2009; Wilkins et al. 2014).

Long-standing experimental breeding of farmed silver foxes has shown these traits will emerge in response to selection for lower aggressive reactivity suggesting the existence of underlying correlatory mechanisms (Trut et al. 2009). Similar behavior-based selection has been shown to have the same effect in other vertebrates, including rats, mink, and chickens. Given most traits of domestication syndrome can be associated, directly or indirectly, with various roles of embryonic neural crest cells, the most widely accepted proximate explanation for this collection of traits is mildly altered function in this cell lineage (Wilkins et al. 2014).

Neural crest cell contributions to the autonomic nervous system, especially the adrenal medulla, and the pituitary suggest an influence on bodily endocrine regulation, which could explain both moderated behavior and shifted developmental processes (Trut et al. 2009; Zeder 2015). As such, major heritable shifts could be accomplished via altered neural crest cell function with only minor genetic mutation. Secondary influence from endocrine change could compound any direct effect of altered neural crest cell behavior on specific tissues, organs, or structures. For example, dampened adrenal reactivity might directly moderate aggressive responses while an extended developmental period could maintain juvenile sociability and cognitive flexibility and both would promote enhanced sociability in adults (Wilkins et al. 2014).

Interestingly, a form of “self-domestication” has been described in wild bonobos (*Pan paniscus*) whose features, in comparison to their near relative, the chimpanzee (*P. troglodytes*), strongly resemble those attributed to domestication syndrome (Hare et al. 2012). In this case, aspects of the bonobo’s socioecology – especially

relatively elevated female social status – are thought to have supported sociosexual selection in favor of less reactively aggressive males.

Human Self-Domestication

Interestingly, multiple authors have suggested that modern humans show signs of domestication syndrome when compared to fossil remains of ancestral *Homo sapiens* (e.g. see: Hare 2017; Leach 2003; Thomas and Kirby 2018; Wrangham 2018). Stated evidence for human domestication includes reduced sexual dimorphism; reduced cranial capacity; smaller tooth sizes; lower skeletal robusticity; reduced craniofacial masculinity and prognathism; and enhanced sociability and social complexity (Cieri et al. 2014; Hare 2017; Leach 2003). Given that selection for lower aggressive reactivity has been experimentally demonstrated to cause domestication syndrome in other vertebrates, similar selection appears likely in human evolutionary history (Cieri et al. 2014; Hare 2017; Wrangham 2018).

Mechanisms explicitly proposed to drive human self-domestication via selection against aggressive reactivity include: (1) social benefits derived from dampened aggressive tendencies which may enhance the fitness of cooperative and sociable group members (Cieri et al. 2014); (2) ostracism or capital punishment of particularly aggressive individuals by cooperative coalitions, which would dampen the fitness of aggressive behavioral traits (Wrangham 2018); and (3) female mating preferences which might select against aggressive males in favor of more sociable individuals with elevated capacity for paternal investment (Cieri et al. 2014; Gleeson and Kushnick 2018). Other modes of selection against reactive aggression, though not previously associated with self-domestication, could include the reproductive benefits of increased alloparenting ability, and selection for enhanced group collaboration during intergroup conflict.

Human self-domestication holds substantial implications for the emergence of human sociability and the study of mechanisms which contributed to it, at individual and collective

levels (Cieri et al. 2014; Hare 2017; Thomas and Kirby 2018). If, as suggested by Cieri et al. (2014), self-domestication has operated by dampening expressions of physiological masculinity, the process would be highly relevant to expanded studies of human social evolution and factors affecting social interaction today. For example, self-domestication research might increase our understanding of sexually differentiated aggression and antisocial behavior witnessed cross-culturally across most human groups.

Conclusion

Domestication syndrome is a heritable physiological condition experimentally demonstrated to emerge in a range of vertebrates under breeding selection for diminished aggressive stress reactivity. Fossilized morphological evidence, along with noted capacities for cooperation and social complexity, points to an evolutionary process of human self-domestication occurring via sociosexual selection for reduced aggression. This phenomenon suggests a cumulative evolutionary influence of past social interaction and implies significant fitness benefits from enhanced social capacity in humans.

Broadly speaking, domestication-related research has a long pedigree of useful contributions to evolutionary knowledge. It has enhanced understanding of relevant selective mechanisms and the underlying physiology of inheritance. An expanding literature on this topic suggests ongoing research into the genetic, physiological, and selective factors associated with vertebrate domestication, and human self-domestication, will continue to provide useful insights for cultural and evolutionary anthropology in future.

Definition

Human sexuality is most broadly defined as the totality of experiences, systems, attributes, and behavior that characterize the sexual sensation, reproduction, and intimacy of *Homo sapiens*.

Introduction

Human sexuality, a remarkably broad topic, is the purview of numerous academic fields and is a discipline unto itself. Scientific perspectives of human sexuality encompass, variously, its reproductive, social, cultural, emotional, and biological aspects. Evolutionary psychologists frame these facets by asking the following question: What is the design of the system – that is, what are the evolutionary forces that have likely shaped the constitution of human sexuality?

The present chapter is focused on human sexuality from the perspective of the evolved nature of mating systems. The main advantage of this focus is that it facilitates broad considerations about the evolutionary biology and psychology of human mating. By the same token, a mating systems approach leaves many aspects of human sexuality unaddressed, namely, those that have less clear implications for reproduction. Omission of a topic does not necessarily reflect a lack of relevant evolutionary research; on the contrary,

evolutionary psychologists engage deeply with all matters of human sexuality. For further reading on sexual diversity or nonreproductive sexuality, please see entries in this volume such as ► [“Evolution of Homosexuality,”](#) ► [“Same-Sex Sexual Behavior,”](#) ► [“Human Copulation,”](#) ► [“Sexual Identity,”](#) and ► [“Sexual Pathology.”](#)

Human Sexuality and the Comparative Approach

Many aspects of human sexuality are unique among species, but usually by a matter of degree than of kind. This general observation has two implications. First, by using phylogenetic comparative methods (for instance, comparing features of human mating to those of the other, extant great apes), one can attempt to draw general conclusions about the likely ancestral makeup of human sexuality. Second, a comparative approach can also reveal instances in which human sexuality meets or violates expectations (for instance, showing ways in which human sexual adaptations are compatible or incompatible with a given mating system). More generally, a comparative approach has value for informing an understanding of the forces that have led to the current state of human sexuality. A comparative perspective is emphasized in Tinbergen’s (1963) “four questions” (about mechanism, ontogeny, adaptive value, and phylogeny) for explaining behavior. Therefore, a recurring tool throughout this entry will be comparisons with sexuality studies in nonhumans.

A Note on Hormonal Mechanisms Underlying Human Sexuality

Endocrine systems constitute an important class of proximate biological mechanisms underlying human sexuality. Hormones are chemical “messengers” that allocate limited physiological and psychological resources throughout an organism. As detailed below, hormones provide some of the physiological background for many of the hallmarks of human mating systems, including pair-bonding, parental care, and mutual mate choice. At a theoretical level, hormones – both independently and in concert with one another – are mediators of an organism’s life history reproductive

strategy, linking physiology, and behavior in the partitioning of energy between mating, parenting, and nonreproductive activities (e.g., Del Giudice et al. 2015). For these reasons, hormonal systems are frequently discussed below within the context of human mating adaptations.

Defining Mating Systems

An understanding of mating systems is core to recreating how human sexuality might have evolved. In brief, mating systems dictate who mates with whom, when, and how often. Mating systems emerge from the cost and benefit male and female experience from mate choice and competition for mating opportunities, which in turn select for male and female adaptations. The details of a mating system can thus suggest selection pressures that forged reproductive behavior. But mating systems also *cause* adaptations, as they affect the reproductive strategies and tactics most beneficial to males and females. Conceptually, therefore, mating systems anchor the various facets of human sexuality discussed below (for an extended discussion of these issues, see Gangestad and Grebe 2015).

Traditional Mating Systems

Mating systems give rise to the nature and degree of reproductive skew, namely, the partitioning of reproduction among members of a society. The following categories of vertebrate mating systems are considered “traditional”:

Monogamy: Males and females have exclusive sexual access to one another.

Polygamy: Sexual exclusivity occurs, but is not monogamous. Three subtypes of polygamy can be discriminated: (a) *polygyny*, individual males have exclusive sexual access to two or more females; (b) *polyandry*, individual females have exclusive sexual access to two or more males; and (c) *polygynandry*, two or more males have exclusive sexual access to two or more females and vice versa.

Promiscuity: Males within a group mate with any and potentially multiple females and vice

versa. A subtype of promiscuity is *dispersed promiscuity*, in which largely asocial individuals with overlapping home ranges mate with multiple partners during brief periods of social grouping (typically, a female’s fertile period; see Dixon 2012).

Monogamy and polygamy assume forms of sexual exclusivity, whereas promiscuity does not. Whereas monogamous mating systems generate variation in reproductive success that is nearly equal across the sexes, polygynous mating systems generate greater male than female variation, and polyandrous mating systems generate greater female than male variation.

Mixed Mating Systems

The traditional categories of mating systems do not exhaustively cover all possibilities; instead, many animal populations exhibit mixed mating systems. In one case, different forms of sexual exclusivity may exist simultaneously. For instance, in avian species typically characterized as polygynous (such that some males mate with two females), monogamous mating arrangements can also occur in the same population. In other cases, different forms of exclusivity may exist temporally or spatially within the same population or species. For instance, individuals of some mockingbird species will mate both monogamously and polygamously depending on available opportunities. Indeed, across the vertebrate species examined, humans included, there is more fluidity in mating system structure than has been recognized historically: Human groups, large and small, have created and can create an array of mixed mating systems.

Selection Pressures Influencing Vertebrate Mating Systems

Traditionally, sexual selection theorists had widely assumed that natural selection would most likely give rise to mating systems characterized by some degree of polygyny. The rationale behind this assumption is known as the “Darwin-Bateman effect”: the increase in offspring number

as a function of the number of matings each male procures with different females, without a similar increase occurring as a function of the number of matings each female procures with different males (see Drea 2005; Parker and Birkhead 2013). Ultimately, the differential effect by sex of “multiply mating” was attributed to anisogamy – sexual reproduction involving the union of “expensive” eggs and “cheap sperm” – and to differences by sex in the initial investment in offspring. In placental mammals, internal fertilization and gestation delays the female’s production of new offspring until after birth, fetal or neonatal loss, and/or some period of lactation; males, however, do not experience these same delays. According to this paradigm, whereas males should benefit from seeking multiple mates, females should reap little, if any, benefit from mating multiply. Under many conditions, therefore, selection was expected to favor multiple mating by males, but only rarely by females, thereby driving an increase in polygynous mating systems.

Polygyny can take on different forms depending on male features that foster access to multiple females (e.g., Emlen and Oring 1977). In resource defense polygyny, males control the resources valued by females for fueling offspring production. In male dominance polygyny, which involves leks (small territories where males congregate to display and attract females), males are chosen by females for their ability to compete with other males, but offer no material resources to females to be directed toward investment in offspring.

In this “Darwin-Bateman” view, monogamy typically evolves when males cannot defend the resources that permit them to attract multiple mates. Ecological constraints explain why, for instance, most birds (over 90%) are socially monogamous: Resources are dispersed to a degree that males cannot typically secure enough for more than one female’s offspring (e.g., Emlen and Oring 1977). However, with the development of genetic tools in the late 1980s and early 1990s, researchers began testing some of the assumptions about traditional mating systems, and avian biologists discovered that many pair-bonding birds actually exhibited high rates of extra-pair

paternity – paternity by males other than the social partner. This finding, which has now been extended to primates also previously thought to be monogamous (e.g., in gibbons: Palombit 1994), prompted the recognition of an *extra-pair mating system*. Although most of the sexual activity occurs within structured units (e.g., individual male-individual female units, individual male-multi-female units, and so on), some mating – “extra-pair” mating – occurs outside of these units. In recognition of the social unit in which most mating occurs, systems with pair-bonding and cuckoldry are said to reflect *social monogamy with EPC* (extra-pair copulation). Some systems entail little EPC, whereas others may entail frequent EPC. Thus, social monogamy with EPC lies on a continuum of degree of sexual exclusivity.

The Polyandry “Revolution” Within Behavioral Biology

Over the past three decades, behavioral ecologists have increasingly recognized the benefits of female multiple mating, which includes EPC in addition to polyandrous mating more generally. Parker and Birkhead (2013) refer to the sea change as a “revolution.” By mating multiply, females could gain both direct benefits that increase reproductive success and indirect benefits that increase the genetic fitness of offspring. Direct benefits can include increased rates of fertilization, increased attainment of resources offered by males, and reduction in male aggression toward offspring via “paternity confusion.” Indirect benefits can include attaining a sire whose DNA is compatible with the mother’s (whereby selection occurs “cryptically” post copulation – within the reproductive tract of the female), diversification of offspring via multiple paternity (bet hedging), and, in the context of extra-pair mating, attaining a sire who potentially has greater genetic fitness (“intrinsic good genes”) than does an in-pair male. As a result of these benefits, female multiple mating is not a rare anomaly; it is commonplace (Parker and Birkhead 2013).

Benefits of Female Multiple Mating

The benefits of multiple mating can arise from multiple sources. To take the example of EPC,

whereas many socially monogamous birds engage in extra-pair mating, it remains uncertain if females in particular derive *any* benefits from it. Males are assumed to benefit from multiple mating, in which case female engagement in EPC may simply reflect male assertion. In some instances, the costs of resisting copulation (e.g., physical harm) outweigh its benefits. Accordingly, EPC can commonly arise exclusively due to male sexual interests and female tolerance, under a scenario of “sexual conflict” (Parker and Birkhead 2013).

Nevertheless, in some avian species, females clearly solicit EPC (e.g., Parker and Birkhead 2013). In this case, the benefits that have the greatest empirical support are direct ones (e.g., parental care, food provisioning). The most controversial interpretation concerns “good gene” benefits. Some researchers conclude that support for genetic benefits of EPC is weak (Parker and Birkhead 2013), whereas others argue that inconclusive data do not necessarily counter a “good genes” interpretation (e.g., Eliassen and Kokko 2008). The jury is still out about whether or not avian EPC functions in a female to gain genetic benefits, and this same uncertainty extends to humans, as noted below in the section “[Women’s Mating Adaptations](#).”

New Models of Sexual Selection Pressures on Males

In recent years, theorists have also questioned the traditional perspective on male interests. In the traditional view based on the Darwin-Bateman effect, males should possess promiscuous sexual motivations and, whenever ecological circumstances permit, compete for the resources or social standing that promote multiple mating. Yet, there are good reasons why males might not pursue this strategy. Males can instead benefit from providing care for their existing offspring. When the net benefits from providing care to offspring exceed the net benefits from competing for mates, males should be selected to care. These conditions are most likely to exist when (a) competing for mates is costly (e.g., males risk injury), relative to the costs of providing care, (b) the net benefits to

competing are relatively weak (e.g., a male is not competitive or many males compete), and (c) the benefits to care are relatively great (e.g., males are able to discriminate their own offspring; offspring benefit from complementary care from males and females) (e.g., Kokko and Jennions 2008).

This framework offers a different perspective on why pair-bonding with biparental care is so common in birds. In the traditional view, the focus is on the male’s inability (e.g., due to resource dispersion) to defend resources supportive of multiple mates and their offspring. In the more recent view, the focus is instead on the relatively poor gain from competing and the substantial benefits to male care (see Kokko and Jennions 2008). In avian species especially, one parent may need to forage, while the other defends a nest of offspring that cannot yet fly. Thus, avian research has drawn attention to the importance of male care and its benefits in the evolution of mating systems – a framework that is broadly applicable to other pair-bonding species, including humans.

Hominoid Mating Systems

The Ancestral State

Applying a comparative perspective draws attention to selection pressures that can drive benefits of multiple mating and of male care – what mating systems characterized ancestral human groups that drove male and female mating adaptations? To address this question, one must consider some of the defining features of primates. Notably, within the primate order, females evolved from the “primitive” mammalian condition of strictly circumscribed sexual receptivity (limited to the 2–3-day peri-ovulatory or fertile period) to a more “advanced” state, evidenced by anthropoid primates, of situation-dependent receptivity. Thus, in female anthropoids, sexual behavior is decoupled from fertility, and females can engage in copulation at any stage of their cycle (Dixon 2012). In those primates that show “extended sexuality” (sexual activity outside of fertile phases), the social system can have significant

influence over sexual behavior, despite the type of mating system. Such is likely to have been the case for our closest ancestors. But what mating system did this ancestral species possess?

Chimpanzee and Bonobo Mating Systems

Whatever mating systems evolved in humans, they originated from adaptations associated with the system(s) of the shared common ancestor with chimpanzees (*Pan troglodytes*) and bonobos (*Pan paniscus*) that existed about 5 million years ago. Chimpanzees and bonobos both live in mixed-sex groups and have promiscuous mating systems, in which females advertise their fertility and show extended sexuality. Females of both species possess hindquarter sexual swellings that serve as “graded signals” of fertility; yet, they are sexually active for a significant portion of their ~30-day cycle, mating with potentially all adult males in the group, typically multiple times. Despite these similarities, these species have highly divergent social organizations that likely impact their sexual strategies. Notably, chimpanzee societies are male dominant and despotic (in which males show female-directed aggression and infanticide), whereas bonobo societies are female dominant, peaceful, and more egalitarian.

In the better-studied chimpanzee, the favored hypothesis for the function of promiscuous mating in females is Hrdy’s (1979): Promiscuous mating confuses paternity. If no male can rule out his own paternity, each is less likely to aggress against the future offspring, thereby reducing the likelihood of infanticide. Nevertheless, there is recent evidence to suggest that the sexual interests of female chimpanzees change across the sexual period. During the non-fertile phase, females are most promiscuous, but during the fertile phase, they tend to prefer particular males (e.g., younger males whose status is rising; Stumpf and Boesch 2005). Perhaps females confuse paternity during non-conceptive portions of their cycle, but when they are fertile, they bias sireship toward males that can offer genetic benefits or certain forms of direct benefits (e.g., physical protection). Indeed, male reproductive success is highly skewed in chimpanzees, with one or two high-quality males

typically siring many more offspring than the majority of other adult males, despite female promiscuity (e.g., Stumpf and Boesch 2005).

In bonobos, female coalitions are considerably more powerful than they are in chimpanzee societies. Female-female sociosexual exchanges regulate female social hierarchies and coalitional activity. It would seem that paternity confusion to protect against the threat of infanticide would be an unlikely explanation for female promiscuity in bonobos; it instead appears to be a mechanism for ensuring social harmony. In no study, however, have researchers yet tested for changes in female bonobo sexual activity or male preferences across the cycle. Despite promiscuity, male reproductive skew is strong, suggesting similar bias in mating with certain males at peak fertility (Gerloff et al. 1999).

Human Versus Pan Mating Systems

As Dixson (2012) notes, humans have diverged considerably from both chimpanzees and bonobos in a variety of respects. In chimpanzees, extreme sexual size dimorphism, rank relations in male androgen concentrations, relative testes size and ejaculate volume, structural features of semenogelin proteins (that coagulate sperm), and length of the female reproductive tract are consistent with the high degree of either male-male competition or sperm competition (multiple males’ sperm residing in the female reproductive tract vying for conception) evident in their social and mating systems, respectively. These features in humans are consistent with lower levels of male-male and sperm competition. Nonetheless, human mating adaptations may possess vestiges of *Pan* mating, as discussed below.

Unique Features of Human Systems

Limits on Reproductive Skew

Hominoids – and humans in particular – have extremely slow life histories, which severely constrains female fertility. Because of the energetic demands of producing highly encephalized infants (and usually only one per pregnancy),

hominoid mothers are heavily invested in their young, assuming costs associated with lengthy gestation and lactation, as well as extended infant and juvenile dependency. Women are especially reproductively inefficient, even “infertile”. Beyond the constraints imposed by the concealed release and short-term survival of generally one egg per fertile period, approximately 50% of human cycles are anovulatory or too short to allow implantation. Women also suffer relatively high rates of conception failure, low embryo viability, miscarriage, premature delivery, and perinatal death (reviewed in Drea 2005).

Coupling women’s extended sexuality with the various physiological constraints on her reproduction, there is enhanced potential in humans for non-fertile mating (Drea 2005; Thornhill and Gangestad 2008). The low probability of conception associated with each copulatory act challenges predictions arising from the Darwin-Bateman paradigm about the almost limitless potential for fatherhood as a function of increasing the number of sexual partners. Brown et al. (2009) examined variance in reproductive success across 18 traditional or preindustrial societies. On average, male variance exceeded female variance (median ratio ≈ 1.70); yet, this ratio varies widely (ranging from <1 to nearly 5).

Mating Arrangements and Sexual Exclusivity

One feature entirely unique to modern humans is the influence of cultural evolution on mating systems. Notably, marriage is a near-universal institution in human societies; despite this ubiquity, marriage does not imply near-universal monogamy (or even serial monogamy) in humans. Ethnographic evidence from the standard cross-cultural sample (SCCS) shows that over 80% of present-day, human societies possess some degree of polygyny. Fewer than 20% are completely monogamous, and 1% are characterized by a nonzero level of polyandry. Agriculture, herding, and other relatively recent means of resource production may alter mating arrangements; Western religious traditions promoting marriage do so as well. Marlowe (2003) examined mating arrangements in the SCCS’s 36 foraging groups and found that about 90% exhibit a

nonzero level of polygyny. Monogamy is, however, still the most typical, socially sanctioned mating arrangement in human societies. In about two-thirds of foraging societies, for instance, the percentage of polygynously married women is 12% or less (Marlowe 2003); in only 13% of these societies does the rate reach 50%.

Nevertheless, marital systems may or may not imply sexual exclusivity. Although most offspring may be produced by in-pair partners, some may be produced through extra-pair matings. Questions of interest, then, are how common is extra-pair sex and how often does it result in extra-pair paternity (EPP). Anderson (2006) reviewed studies estimating nonpaternity, largely in developed countries. Nearly all samples give biased estimates, depending on how they were selected. High paternity confidence samples estimate an EPP rate averaging just 2%. Samples of men who suspicion about their partner’s fidelity estimate it to be, on average, about 30%. Once again, tremendous variation exists, ranging from $<1\%$ in high paternity confidence samples (in Switzerland and Germany) to about 12% (in Monterrey, Mexico). For some other traditional societies, ethnographies report very frequent EPC, but systematic data on EPP rates are scant (Anderson 2006). Within developed countries, extra-pair paternity rates have declined in the past century; the advent of effective birth control may reduce incidence of conceptive EPC, suppressing the EPP rate. In traditional settings, then, EPP rates may have been low on average (5% or less) but variable (in some societies $>10\%$).

As with females of other species, the benefits that give rise to women’s extra-pair mating are debated. Some scholars argue that benefits lie largely (or even exclusively) with male extra-pair partners, while others stress the possibility that women too, in many circumstances, benefit (for a review, see Thornhill and Gangestad 2008).

Offspring Care

Consistent with slow life histories, human offspring are, in many respects, remarkably altricial at birth. Compared to other hominoids, humans are born with extreme motor immaturity and brains that represent a relatively small proportion

of adult size. As in other primates, human mothers harvest the overwhelming majority of calories consumed by offspring during pregnancy and lactation. For periods longer than in any other primate (i.e., including postweaning), however, human infants continue to be dependent on mothers and others for food, protection, and social development. Because of their extended dependency and juvenility, evolutionary theorists argue that early humans developed a system for rearing their young (and, thus, ensuring their own reproductive success) in which mothers, along with various helpers, cooperate in raising infants (Hrdy 2009). These adaptations for care stem from the nature of human mating systems and life history that inform the likely structure of ancestral human sexuality.

Mothers and Allomothers

The maternal bond or mother-infant relationship is one of the strongest across mammalian species. Its development, which begins in pregnancy, is influenced by the hormone oxytocin (OT). Most generally, OT (along with related homologs in nonmammalian taxa) is a smooth muscle contractor that plays a highly conserved role in orgasm and sexual functioning, as well as in parturition and lactation. OT also functions as a neurotransmitter involved in establishing and maintaining maternal behavior (see Gangestad and Grebe 2017). It is thought that OT's role in maternity constitutes the "biological prototype" for its functions in facilitating other kinds of social bonds so critical to human society (see section on "[Pair-Bonding and Oxytocin](#)").

Many have argued that the extended period of infant care is intricately linked to the early termination of fertility in women – that the distinct post-reproductive period (i.e., menopause) that characterizes human females allowed reproductively senescent mothers to better ensure their latest progeny's survival and overall reproductive success, relative to aged mothers who continued to engage in risky pregnancies. This "stopping early" hypothesis has been contrasted with the "grandmother hypothesis" that instead proposes that senior women contribute best to their own inclusive fitness by investing in the reproductive

success of their childbearing daughters. Accordingly, the diets of women of reproductive age and their children are subsidized, not primarily by the women's mates, but through the efforts of maternal kin – most importantly, the mothers' mothers (Hawkes 2003).

Paternal Care

Questions intensely debated within evolutionary anthropology over the past two decades include whether human pair-bonding is central to the mating system and whether males possess adaptations for providing care for offspring. Did ancestral conditions that favored male care, at least contingently, exist recurrently in human groups, leading natural selection to shape male features that promoted care? Although pair-bonding need not imply biparental care, the two are strongly associated in the animal world. Male care potentially comes in many forms: Protection, direct care (e.g., supervision), and provisioning are three prominent categories. In the anthropological literature, two research areas have received significant attention: the role of testosterone (T) in men's parenting effort and the importance of men's hunting in provisioning mates and offspring.

Parenting Effort and Testosterone

Across vertebrate taxa, T is a crucial component of a system that functions to facilitate male mating effort by channeling energetic resources to features particularly useful in male-male competition (e.g., muscles, sensitivity to dominance ranks, and cues of social hierarchy) and, due to necessary trade-offs, away from other targets of allocation (e.g., repair, immune function; see Bribiescas 2001). In species in which males exert parental effort, a modification may have evolved: T may also modulate allocations of effort to mating versus parenting (in shorthand, competing vs. caring). In some species in which males invest in offspring (e.g., marmosets, some birds), male T concentrations drop after the birth/hatching of the mates' offspring (discussed in Bribiescas 2001; also see section on "[Mating \(Versus Parenting\) Effort and Testosterone](#)").

Views About Hunting as “Parental Effort”

In most primate species, individuals of both sexes are largely responsible for their own subsistence after at most a few years after birth. In most human foraging populations, however, the average adult male generates more calories than he consumes, with the surplus being distributed among kin and, in some cases, non-kin group members. The primary activity through which men generate surplus calories in foraging societies is hunting (broadly defined to include any activity, including fishing, aimed at harvesting animal meat). Although women forage and extract roots (and, in a meaningful minority of societies, produce more calories than do men), only rarely do they hunt to a substantial degree. Human foragers appear to be adapted to a diet consisting of high-quality, calorie-rich foods. Whereas chimpanzees obtain about 95% of their calories from collected foods requiring no manual extraction (e.g., fruits, leaves), only about 8% of calories consumed by modern hunter-gatherers are from foods requiring no manual extraction, with a large proportion (30–80%) derived from vertebrate meat. The level of male contribution to the diet varies considerably across foraging societies (~40–90+%). Women reproductively benefit from the male-generated surplus. Women’s offspring production or, specifically, their inter-birth interval – the delay between the birth of one offspring and the same woman’s next offspring – is aided by male contribution to subsistence (Marlowe 2001).

Thus, a traditional anthropological view is that male surplus food production evolved as paternal care. According to this view, the nuclear family is a key economic unit in the evolution of human mating relations. For subsidies generated by male hunting to function as parental effort, nutrients that men generate must flow to their mates (and then to offspring) or directly to offspring. Additionally, if one adopts the perspective of T as a mediator of mating versus parenting effort, this view of hunting as an instantiation of paternal care suggests it should be associated with T decreases. An alternative view of hunting – in that it primarily functions as an activity to gain new mates – is discussed below in the section “[Views About Hunting as “Mating Effort”](#).”

Adaptations for Mating

In general, patterns of human mating and reproduction are consistent with human pair-bonding and biparental investment, albeit with modest levels of polygyny, nonzero rates of EPC, and notable variability. How do these patterns inform male and female adaptations for mating? These features, in some instances, serve as telltale signatures of the mating system that led them to evolve. The subsections below address evolutionary forces and mechanisms that (a) contribute somewhat equally to mating adaptations in both sexes, (b) are most directly relevant to men’s mating adaptations, and (c) are most directly relevant to women’s mating adaptations.

Mutual Mate Choice

In species in which male and female pairs bond, “mutual mate choice” typically evolves. Members of both sexes are advantaged through preference of some mates over others (e.g., Kokko and Jennions 2008). Studies of mate preferences strongly point to mutual mate choice in modern human societies. In many instances, choice for mates that exhibit good parenting qualities should be preferred. In seeking a long-term mate, both men and women, on average, rate “kindness and understanding” as the top preference. Many other mate preferences for personality traits, however, are characterized by large sex differences (see Conroy-Beam et al. 2015).

Specific forms of mate preference offer particularly compelling examples of adaptation for mutual choice. The human leukocyte antigen (HLA) system, for example, which controls the immune response and pathogen resistance, has been correlated with both odor preferences and, to a lesser extent, facial preferences in potential mates (Winternitz et al. 2017). The HLA is a highly variable gene complex encoding the major histocompatibility complex (MHC) proteins in humans. MHC genes code for cell surface markers that function to “declare” that a cell is uninfected (when the MHC molecule presents only self-peptides) or infected (when the MHC molecule binds a non-self-peptide structure that is “visible” to the immune system). All else

being equal, it pays to mate with someone who possesses alleles optimally different from one's own, either to avoid inbreeding or to produce advantaged heterozygotic offspring. MHC appears to be detectable through signatures in scent (or facial attractiveness). In a variety of species, females prefer the scent of males that possess MHC genes different from their own. Studies strongly suggest that humans too are most sexually attracted to scents of others who possess non-shared MHC alleles. Consistent with *mutual* mate choice, preferences typically exist in *both* sexes (reviewed and meta-analyzed in Winternitz et al. 2017). Evidence for mutual mate choice also exists in the domains of voice pitch and facial symmetry, perhaps because these traits too are cues of the bearer's condition (of which MHC complement is only one feature; see Thornhill and Gangestad 2008).

Pair-Bonding and Oxytocin

As discussed above (see section on “[Offspring Care](#)”), OT plays a major role in the formation of social bonds; its role in pair-bonds has become a hot topic within social psychology. Classic comparative studies in voles were the first to implicate OT in sexual pair-bonding, showing that brain neuroanatomy and central nervous activity of the OT system underlie the development of monogamous partner preferences. From this foundation, psychologists have recently begun to examine how OT plays a role in human sexual pair-bonding. Some evidence is consistent with a pro-social role for OT in romantic bonding in both sexes. OT administration leads to more engaged, constructive communication about relationship conflicts and more intense orgasms and greater contentment after intercourse with a pair-bond partner. Success of relationship interventions and overall relationship satisfaction are related to OT concentrations, and both men and women in newly involved couples exhibited high serum concentrations of OT (see Gangestad and Grebe 2017).

In other studies, OT has been linked to distress and attachment anxiety in romantic relationships. These conflicting results reflect a more general uncertainty regarding the overarching function

of OT in social behavior (see Gangestad and Grebe 2017). As one possible resolution, it may be that threats to valuable, vulnerable relationships are key triggers of the OT system. This hormonal increase, in turn, then functions to reorient psychological resources toward these relationships. Preliminary evidence from both men and women in romantic bonds is in line with such an interpretation, further suggesting that the role of OT in pair-bonding is central for both sexes. A focus on relationship vulnerability may also generalize to other social bonds regulated by OT – in particular, the mother-infant relationship (see Gangestad and Grebe 2017).

Men's Mating Adaptations

Mating (Versus Parenting) Effort and Testosterone
Evidence from nonhuman studies are consistent with a T-mediated hormonal system that is sensitive to the relative value of exerting mating versus parental effort. There is increasing evidence to suggest men's T mediates a similar trade-off. Men with higher T concentrations exhibit greater frequency and intensity of male-male competition, dominance behavior, and mate seeking; in contrast, men who are mated or have offspring typically have lower T concentrations than do single, childless men (reviewed in Gray and Campbell 2009). Some evidence indicates that the association depends partly on changes in T concentrations following changes in mating or paternal status. Additionally, among fathers, those with lower concentrations of T and smaller testes show a pattern of brain activation when looking at photos of their own children, indicative of greater paternal involvement.

The effect of mating status on men's T concentrations is moderated by men's interest in pursuing extra-pair relationships with women other than their primary partners. Men who have little interest in or history of extra-pair relationships reveal the typical drop in T concentrations when mated, as compared to their concentrations while single. Men who have interest in extra-pair relationships, by contrast, showed no difference: Their T concentrations were just as high when in relationships as when single (see Gray and Campbell 2009).

Paternity Certainty and Male Care

Because male confidence in paternity is variable, men's parental efforts may be contingent on cues of paternity, such as self-resemblance. In a large Western sample, men assisted offspring they report as likely to be their own genetic offspring more so than those they suspect reflect EPP (Anderson et al. 2007). Behavioral researchers have examined possible psychological underpinnings of discriminative parenting. In one design, a digital photograph is taken of a participant. The participant's own face or, alternatively, that of another participant is digitally combined with the face of a small child to create two composite images of child faces – one “self-resembling” and one not. Participants then choose between the children based on their likelihood of investing in (e.g., spending time with, adopting) each child. Men consistently prefer the self-resembling one, an effect not due to conscious recognition of self-resemblance (reviewed in Thornhill and Gangestad 2008).

Views About Hunting as “Mating Effort”

The theory of male-hunting-as-parental-effort, discussed above, faces a fundamental difficulty: Nuclear families are not, in fact, potent economic units in foraging societies. In the Hadza of Tanzania and the Ache of Paraguay, for instance, hunters have little control over the distribution of the meat they generate. Instead, meat (particularly from large game) is shared widely across community members. A Hadza hunter's own family receives no more meat from his large game kills than what it receives from the same-sized animal a neighbor killed. In one analysis, offspring nutritional status covaried with Hadza women's foraging returns, but not with men's returns. Thus, perhaps men's hunting functions as (i.e., is adapted for) mating effort – effort to compete for access to mates through “showing off” – rather than as parental effort. Men garner prestige through successful hunting exploits, particularly big-game hunting, and this prestige translates into mating opportunities.

Of course, male hunting subsidizes the diets of women and their offspring. But these subsidies, in

the male-hunting-as-mating-effort view, are not generated directly by the women's own mates or by the children's own fathers. Rather, they are generated through the efforts of men in general to gain mates. The surplus calories generated by male hunting that benefit women and offspring are by-products of men's showing off – windfalls they enjoy, not benefits men's efforts were designed to achieve.

A Blended View on Hunting in Relation to Human Sexuality

Historically, men may have benefited from hunting in currencies of enhanced viability of offspring *and* mating opportunities (e.g., Gurven and Hill 2009). Patterns of Hadza foraging rates and activities support this relationship (Marlowe 2003). Overall, married Hadza women produce as many calories as do married Hadza men. Women with young children, however, do not, because their childcare interferes with effective foraging. In such circumstances, their husbands forage more than they do; in couples with an infant less than 1 year of age, men produce almost 70% of the total calories generated within the family unit. Hadza men's work efforts (and prey items targeted) adjust in response to the direct food production of wives and the presence or absence of young children. The view that men's work functions solely as mating effort cannot readily explain this pattern.

Other data also support this blended view. Across societies of the standard cross-cultural sample, pair-bond stability (low divorce rate) associates with children being weaned at older ages. Because lactation interferes with women's ability to collect food, male subsidy purportedly permits women to invest in young offspring through nursing. Additionally, if men contribute to the household's consumables, male total contribution to calorie production should predict greater levels of monogamy across societies. This prediction is supported by the available anthropological evidence (see Marlowe 2003; Thornhill and Gangestad 2008).

Women's Mating Adaptations

The Ovulatory Cycle

Women, like the vast majority of other mammalian females, undergo regular cycles that restrict the window in which successful conception from sexual intercourse is possible. It is thought that these cycles arise, at least in part, because (1) substantial time is required to prepare the uterus for implantation and (2) the production of germ cells and behavioral adaptations essential to ensure conception from sexual intercourse are physiologically exhausting. Periodicities in sexuality are regulated by a concert of hormonal changes, involving luteinizing hormone, follicle-stimulating hormone, estradiol (E_2), and progesterone (P_4). Together, these hormones function to ensure successful conception, gestation, and parturition (reviewed in Dixson 2012). E_2 and P_4 have received substantial attention for their roles in the psychology of women's mating as well (for a review, see Roney 2015).

Mating Effort and Estradiol

In line with other phenotypically integrated hormonal systems, E_2 's psychological effects "go along" with its physiological roles to regulate energy allocation – in this case, toward females' mating effort, perhaps at the expense of other activities, such as feeding (see Roney 2015). Historically, some sexuality researchers have argued that E_2 has little, if any, impact on women's sexual behavior, noting, for instance, that the effect of ovariectomy on women's sexual behavior is less than the effect on comparable sexual behavior in other female primates (Dixson 2012). In the most robustly designed study to date, however, researchers sampled women continuously throughout multiple cycles and found that E_2 does, in fact, predict overall levels of female sexual desire (reviewed in Roney 2015).

Social Bonding and Progesterone

The role of P_4 in human sexual behavior has received relatively less attention. Dixson (2012) reviewed studies involving the administration of

P_4 to female nonhuman primates, in which the general finding was that P_4 diminishes sexual receptivity and proceptivity. Roney (2015) argues that because women's P_4 concentrations associate negatively with subjective sexual desire, P_4 is a "stop signal" for sexual motivation that facilitates a shift toward other activities. An alternative viewpoint is that P_4 modifies the nature of sexual motivation. P_4 is most consistently elevated at two times: during the luteal phase and during pregnancy. During these non-conceptive phases, in which women still initiate and accept sexual advances, P_4 may have been selected because it shifted sexual interests to allow focus on pair-bond relationships, perhaps especially when the male partner's interest in the relationship lags behind that of the woman (Gangestad and Grebe 2017). During pregnancy, women may have particularly benefited from consolidating social support from a pair-bond partner, kin, or trusted friends. Preliminary evidence is consistent with an interpretation of P_4 facilitating bonding in a *targeted* manner, rather than it contributing to generalized affiliative motives (see Gangestad and Grebe 2017).

Cyclic Shifts in Women's Mating Behavior and Preferences

Whereas ovarian hormones may be the proximate biological factors thought to underlie changes in women's sexuality, cycle phase (i.e., fertile vs. non-fertile windows) provides a relevant functional distinction for understanding adaptations in women's sexual behavior. Changes in concentrations of E_2 and P_4 that result from the physiology of the ovarian cycle convey information, via the neuromodulatory effects of these hormones, related to fecundity (i.e., the probability of successful conception and gestation). Presumably, because the costs and benefits of sexual activity differ depending on whether or not conception is possible, women's mating adaptations should shift accordingly. A substantial literature has accumulated addressing if and how women's sexual preferences and behavior shift as a function of where they are in their cycle.

In most vertebrate species, females are only sexually receptive during their fertile reproductive phase. Consistent with early views about the minimal influence of E_2 on women's sexuality, initial accounts on the evolution of human sexuality minimized or entirely discarded the idea of a distinct fertile-phase sexuality in women, proposing that it was lost and replaced by continuous, unchanging sexual receptivity across the ovarian cycle. Decades of empirical research have since shown that while sexual *frequency* may not always vary across the ovulatory cycle, women's sexual *behavior*, *preferences*, and *interests* clearly do change (see Thornhill and Gangestad 2008). In an impressive longitudinal study following over 400 naturally cycling women, Arslan et al. (2017) found that women in the peri-ovulatory period, compared to during non-fertile phases, reported increased extra-pair sexual desire and behavior, in-pair sexual desire, and self-perceived desirability. Additionally, when fertile, women may be more attracted to certain male features, such as masculine bodies and behavioral dominance. And, should the women's primary partners lack those desired features, fertile women (only) report greater attraction to men other than their partners (findings reviewed and meta-analyzed in Gildersleeve et al. 2014). Thus, one possibility is that women's fertile-phase sexuality is attuned to certain male features when fertile – namely, those that represent “good genes” that could be transmitted to offspring (Thornhill and Gangestad 2008). In cases in which primary partners lack these features, women's mating adaptations could facilitate EPCs. Nonetheless, other possibilities cannot be ruled out: First, these preferences may reflect adaptive mate choice without any selection for EPCs per se; second, women may have retained a vestigial form of estrous-related sexual interests that carry little adaptive significance (e.g., Thornhill and Gangestad 2008).

Women also exhibit extended sexuality to an extreme degree: In addition to potential receptivity and proceptivity throughout the cycle, women's frequency of sexual intercourse changes little depending on where they are in their cycle (Thornhill and Gangestad 2008). In chimpanzees, the prevailing explanation of extended sexuality is

that non-conceptive sexual behavior functions to confuse paternity and prevent infanticide by males (see above; Hrdy 1979); however, women's extended sexuality does not function in this way. Rather, emerging evidence suggests that sexual interests during the non-conceptive phase function, at least in part, to elicit investment and benefits from male pair-bond partners (see Gangestad and Grebe 2017). This account perhaps provides another example of an adaptation for pair-bonding in the human lineage.

Conclusion

What can be concluded about the evolved nature of human sexuality, as it has shaped human adaptations for reproduction?

First, humans likely evolved systems in which pair-bonding has been important and in which men often exert considerable effort to invest in offspring (e.g., Dixson 2012; Thornhill and Gangestad 2008). Monogamy or serial monogamy is the most frequent mating arrangement, especially when male contribution to subsistence is great, but most human societies possess some degree of polygyny. Both men and women possess adaptations that serve as telltale signs of selection in favor of pair-bonding and paternal investment, but both also exhibit features that suggest some degree of adaptation for short-term mating bonds. Indeed, although typically occurring at low frequencies, nonzero rates of EPP characterize most human groups. Female benefits to EPC are not fully understood and may or may not include genetic benefits.

Second, despite these general patterns, wide variations across human groups exist in degrees of monogamy, sex differences in reproductive skew, and EPP rates. Some variation derives from flexibility in which group members invest heavily in offspring: Reliance on paternal contributions fosters monogamy and relatively low EPP rates; heavy reliance on maternal kin (arrangements of communal breeding) likely leads to increased EPP rates.

Third, human mating systems possess some similarities to the mating systems of several of

our close ancestors, including chimpanzees and bonobos, but the differences also cannot be denied. Evolutionary biologists have intensely debated the order in which humans proceeded through specific primate-like mating systems, as well as the events and adaptations which eventually spurred a transition to the contemporary systems displayed by humans. There is no clear consensus on this issue, although further research may lead to future insights.
